Various authors have investigated concentration of casein either with ultrafiltration (all protein is in that case concentrated to reduce the liquid flow in the cheese production lines) or microfiltration, which allows for concentration of casein over serum protein. When focusing on this latter option, four studies are illustrative for what is possible, as shown in Table 2. The obtained process conditions were very comparable with the exception of the work of Krstic et al. (2002) who used turbulence promoters, but also did not reach high concentration factors. In general it can be said that for concentration of casein micelles, control over the membrane flux and related fouling are the most important factors to keep into account and that high concentration factors of up to 10 are feasible.

The individual serum proteins have many different applications, as have their hydrolysates that are known to contain bioactive components. Since hydrolysates are much smaller than the proteins, they can be easily removed through ultrafiltration. Separating the whole protein from a

Serum Proteins, Table 1 Concentrations and sizes of proteins present in milk (Walstra et al. 1999)

	Concentration in whole milk (g/l)	Average molecular size or weight
Total serum proteins	0.7	3–6 nm

mixture is still a challenge; α -lactalbumin may, for example, first be thermally aggregated, prior to membrane ultrafiltration; alternatively also adjustment of pH and salt concentration can be used to influence electrostatic and steric interaction and in this way enhance the selectivity of ultrafiltration as described in, e.g., Cheang and Zydny (2003).

Shear Stress, Control Fouling with

Pierre Le-Clech

School of Chemical Engineering, The University of New South Wales, UNESCO Centre for Membrane Science and Technology, Sydney, NSW, Australia

One of the main strategies used to limit concentration polarization and fouling in membrane processes is to increase the shear stress in the vicinity of the membrane surface, so to enhance the mass transfer of foulants away from the separating interface. The deposition of particulate materials on membrane surface generally occurs when the local flux of a particle exceeds its critical value, which is strongly dependent on the characteristics of the particle and the overall operating conditions (i.e., hydrodynamics), affecting shear stress.

For example, high concentration of foulants results in increase in feed viscosity and, in turn, in decrease in the rate of diffusion coefficient to the feed (and the resulting Brownian back-diffusion) (Belfort et al. 1994). In addition, phenomena like shear-induced diffusion (i.e., migration of interacting retained particles in the direction of decreasing particle concentration) and inertial lift (i.e., motion of particles across a nonuniform shear field to an equilibrium position away from the channel wall) have also been described as back transport mechanisms provided by shear stress.

In biologically based membrane systems, like membrane bioreactors (MBRs), the transport,

Shear Stress, Control Fouling with, Fig. 1 Example of CFD modeling shear rate on membrane surface within spiral wound feed spacer (*top and bottom* colors: *red* is positive, *blue* is negative, and *green* is zero); inside colors

are salt concentration; *arrows* are sized and colored according to velocity magnitude (*red* is higher, *blue* is lower) (Picture supplied by Dr Gustavo Fimbres Weihs, UNSW, Australia)

adhesion, and bio-growth of bacterial cells are also strongly impacted by shear stress (Cui et al. 2003). Detachment of the biofilm results from interfacial transfer process, with diffusing cells from the biofilm back to the bulk liquid. As expected, biofilm detachment is observed to increase with both fluid shear stress and biofilm mass. However, other factors such as the limited availability of nutrients can also increase rate of biofilm detachment.

Implementation of High Shear Stress

In conventional pressure-driven membrane systems, the implementation of high shear stress is generally delivered through elevated flow rate of the feed stream and the use of feed spacers, increasing turbulence on the membrane surface.

Air scouring is generally used to control fouling in MBRs, and the effects of the two-phase flows circulating on the membrane surface have been extensively reviewed (Cui et al. 2003). In the case of hollow fiber MBR, aeration also results in fiber movement, which limits the deposition of materials on their surface. It is now generally accepted that, once a certain airflow rate is exceeded, no further significant fouling limitation is observed. Although few studies have indicated the greater performances obtained with small-size

bubbles, the large majority of the literature acknowledges that large bubbles create relatively more turbulence and, therefore, present a better option for antifouling strategy (Böhm et al. 2012).

Characterization of Shear Stress

Precise characterization of the shear stress in real membrane configurations is challenging and is generally limited to academic studies. Many research groups have developed elaborated computerized fluid dynamic (CFD) models to describe shear stress at micro- and macroscales. CFD studies have also been widely used to better describe flow patterns in narrow spacer-filled channels, like in spiral wound configurations generally found in reverse osmosis. These works have generally resulted into optimization of spacer geometric parameters and into better characterization of mechanisms responsible for mass transfer enhancement (Fig. 1). While two-dimensional (2D) flow models have been studied for a couple of decades, 3D solutions are also slowly emerging (Fimbres-Weihs and Wiley 2010).

However, in order to estimate shear forces in their membrane systems, practitioners tend to rely on simpler parameters, such as estimated cross flow velocities, Reynolds numbers calculated from bulk parameters like liquid flow rates

(obtained from pumping equipment), and dimensions of membrane vessels or modules. However, only very rough estimation can be obtained, with little opportunity to truly optimize and/or better understand their membrane operations.

- membrane, (b) dissociation of the gas molecules on the surface of membrane, (c) dissolution of gas atoms into the metal bulk, (d) diffusion of gas atoms through the metallic layer, (e) association of gas atoms at the other side of the membrane, (f) desorption of the gas molecule from the surface of the membrane, and (g) external diffusion of the gas molecule to the gas bulk (Gallucci et al. 2013).
- In general the permeation of H_2 molecules through a Pd-based membrane (Basile and Gallucci 2009) follows:

$$J_{H_2} = \frac{P}{L} \left(P_{H_2, \text{retentate}}^{n_m} - P_{H_2, \text{permeate}}^{n_m} \right)$$

where J_{H_2} is the flux of H_2 through the membrane, P is the permeability of the membrane, L is the thickness of the metallic selective layer (Pd layer), $P_{H_2, \text{permeate}}$ is the partial pressure of hydrogen in the permeate side (the side that contains the permeated gas with lower pressure) and $P_{H_2, \text{retentate}}$ partial pressure of H_2 in the retentate side (the retained gas stream with higher pressure), and n_m is an exponent that depends on the rate-limiting step in the permeation phenomenon. At the presence of a thick selective metallic layer (Pd layer), diffusion of the gas atoms through this layer is the rate-limiting step, and n_m value will approach to 0.5. The reason is that the diffusion rate through the metal is proportional to the concentrations of H atoms on opposite sides of the membrane and this concentration is proportional to the square root of H_2 in permeate and retentate sides. In this case, the flux can be described by Sieverts' law (Yun and Oyama 2011).

In case of very thin selective layer (supported membranes with high fluxes), external mass transfer limitation (steps a and e) could be a limiting step (Tiemersma et al. 2006; Caravella et al. 2009). In this case, the value of n_m exponent will approach to 1. The reason is that in this case the permeation through the membrane will be proportional to the concentration of molecular hydrogen. At the presence of high flux through the membrane, the concentration of H_2 molecules close to the membrane will be lower than the value in the bulk of the flow. This phenomenon is generally named as concentration polarization

Sieverts' Law

Arash Helmi

Department of Chemical Engineering and Chemistry, Chemical Process Intensification, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

Adolf Sieverts (1874–1947) published an article in 1929 discussing the absorption of gases by metals and proposing a rule to describe this phenomenon (Sieverts 1929). According to Sieverts' law, the solubility of diatomic gases (such as H_2 , N_2 , and O_2) in metals is proportional to the square root of the partial pressure of the gas in thermodynamic equilibrium (Gupta 2003). In membrane science, the Sieverts' law is widely used to describe the permeation of H_2 through dense metallic (Pd-based) membranes via a solution-diffusion mechanism (Basile and Gallucci 2009). In general the transport of the gas (H_2) molecules from a high-pressure region to a low-pressure region follows several steps: (a) external diffusion of the gas molecules to the surface of the

which will result in lower performance of the membrane. n_m values greater than 0.5 might happen also in case of a tick defected membrane (pinholes on the surface of the membrane) where other permeation mechanisms as Knudsen diffusion or Poiseuille flow will play a role. In general the value for n_m should be measured experimentally with a defect-free membrane (Caravella et al. 2010).

Impurities (such as CO) in the feed gas stream can also deteriorate the performance of the membrane. This will result in lower permeation of H₂ through the membrane at the presence of certain amount of CO and will determine deviations from the Sieverts' law. Increasing the temperature will result in lower effect of CO on the permeation through the membrane (Scura et al. 2008).

Zeolite is an aluminosilicate mineral and possesses different crystal structures that determine the pore diameters, which vary between 0.3 and 1 nm (Hedlund 1998). Cavities and pores are uniform in size within a specific zeolite material and permit only molecules of certain size and shape to penetrate inside the channels and reject those of larger dimensions. This type of separation is termed as molecular sieving. Therefore, small-pore 8-ring window zeolites were developed for the separation of light gases. An example of such zeolite is all-silica decadodecasil 3 rhombohedral (DDR) with a window opening of 0.36×0.44 nm (Gies 1986). The topology of all-silica DDR consists of window-connected cages in the absence of aluminum, in contrast to zeolite frameworks, which makes this material a member of the group of clathrasils. Clathrasils are all-silica clathrate compounds with three-dimensional frameworks built of $[\text{SiO}_4]^{4-}$ tetrahedral linked in the corners with cage-like voids in between (Zhu et al. 2000). All-silica DDR can be considered as a link between zeolites and clathrasils because it possesses zeolitic properties through a clathrasil structure. The chemical composition of all-silica DDR can be represented as $[(\text{C}_{10}\text{H}_{17}\text{N})_6(\text{N}_2)_9][\text{Si}_{120}\text{O}_{240}]$, where $\text{C}_{10}\text{H}_{17}\text{N}$ is 1-aminoadamantane used as a template molecule in the synthesis.

The preparation of all-silica DDR membranes have been widely reported (Tomita et al. 2004; Bergh et al. 2008; Kuhn et al. 2008). As a general

Silica DDR Membrane, Fig. 1 SEM images of the microstructure of a DDR type zeolite membrane formed on a porous alumina substrate, (a) surface and (b) cross-

section (Tomita et al. 2004). Reprinted with permission from ref. Tomita et al. 2004. Copyright 2016, Elsevier

procedure of synthesis, all-silica DDR seed crystals are initially deposited on the surface of porous alumina substrate prior to the immersion in mixture solution of 1-aminoadamantane agent to grow a continuous DDR membrane and followed by the calcination process at high temperature ($\sim 700^\circ\text{C}$). The general microstructures of the resulted all-silica membrane are shown in Fig. 1. This figure indicated that dense all-silica DDR membrane was formed uniformly and the thickness of the membrane was 5–10 μm . The porous alumina substrate was commonly used as a support to provide high mechanical strength and low flow resistance to the membrane.

According to Bergh et al. (2008), the permeation and separation characteristics of light gases through all-silica membranes can be explained by taking into account three factors, which are (1) steric effects introduced by the window opening of all-silica DDR leading to molecular sieving and activated transport, (2) competitive adsorption effects, and (3) interaction between diffusing molecules in the cages of the zeolite.

Pore dimension of 0.36×0.44 nm allowed the all-silica DDR membrane to be very suitable for the separation of CO_2 and CH_4 , which have kinetic diameters of 0.33 and 0.38 nm, respectively. As reported by Tomita et al. (2004), the separation factor (SF) of CO_2 to CH_4 in 50 % CO_2 and 50 % CH_4 mixed gas feed for the synthesized all-silica membrane was in the range of 100–220 at 0.5 MPa total gas feed pressure,

which is much higher than that of other types of zeolite membranes such as FAU-type zeolite membrane (SF 20) (Kusakabe et al. 1997), MFI-type zeolite membrane (SF 16) (Lovallo et al. 1998), SAPO-34-type zeolite membrane (SF 30) (Poshusta et al. 2001), and LTA-type zeolite membrane (SF 0.5) (Aoki et al. 1998). Apart from its high potential in CO_2/CH_4 separation application, all-silica DDR membranes are also a good candidate for the separation of nitrogen/methane (SF 20–45), carbon dioxide and nitrous oxide/air (SF 20–400), and air/krypton (SF 5–10) (Bergh et al. 2008).

Silica Gel for Membrane Preparation

Silica gel is composed of silicon oxide manufactured widely for moisture removal. It is typically in solid form and possesses high ability in water absorption. The used silica gel can be regenerated by heat treatment at temperature range of 100–120 °C for several hours. In

addition, it is also a stable material, nontoxic, and easily available and inexpensive. Commercial silica gel typically has high surface area, large total pore volume, and broad pore size distribution (Wang et al. 2012). These characteristics produce less resistance for gas/liquid to diffusion into it and thus make this material potentially to be used as a membrane material.

Silica gel can be prepared via a chemical reaction between sodium silicate with an acidic solution at constant pH (Greenwood and Earnshaw 1997). To produce silica gel for commercial uses, a gelatinous precipitate obtained from the reaction is washed prior to the dehydration process to produce colorless silica gel. Typically, cobalt chloride or ammonium tetrachlorocobaltate is added to silica gel to give a visible indication of its moisture content (Greenwood and Earnshaw 1997).

However, for membrane fabrication process, silica gel can be synthesized using polycondensation of hydrolyzed tetraethoxysilane (TEOS) under acidic conditions through a sol-gel approach (Lavorgna et al. 2007; Mishra et al. 2012). This method is more favorable because high-purity silicate glasses can be obtained. Similar to other ceramic material, silica gel has hydroxyl group on its outer surface which enables anchoring process to be carried out effectively. This process is also known as functionalization which is a crucial step in the fabrication of membrane on the top of silica gel support which facilitates the intimidation between these two layers.

Various organic chemicals are used to functionalize silica gel, and the method to obtain chemical bridge between support and membrane might be different among research group. However, there is a general consensus in the way of functionalizing silica gel such as removal of moisture prior to functionalization process, stirring and mixing process between precursor of chemical bridge and silica gel, and washing and drying cycle using alcohol (Lavorgna et al. 2007). These preparation steps are rather simple without the necessity of using complex methods and advance equipments.

Silica gel has been recognized as a promising additive material in polymeric membrane for fuel cell application (Mishra et al. 2012). Due to its

high hydrophilicity in nature, it has been used to increase proton conductivity of commercial fuel cell electrolyte membrane, i.e., Nafion[®], and retain humidity when the membrane is used at temperature higher than 80 °C (Mishra et al. 2012). The incorporation of silica gel into polymeric membrane can be accomplished by adding the silica gel into polymeric solution prior to the casting step and the drying process (Mishra et al. 2012; Seo et al. 2006). This approach enables the silica gel to be homogeneously dispersed across polymer matrix. However, the functionalization of silica gel should be carried out prior to this process. On the other hand, the silica-based composite membrane can be fabricated by impregnation process (Mishra et al. 2012; Mahreni et al. 2009). This can be achieved by soaking the membrane by silica sol followed by functionalization process. These two approaches can be categorized as *ex situ* approach in producing composite membrane for fuel cell application. There is another approach known as *in situ* technique which involves the incorporation of either nanoparticles or their precursors into monomer solution with low viscosity (Mishra et al. 2012). This approach ensures better dispersion and physical properties but very little information can be obtained from open literature (Mishra et al. 2012). It is perhaps that this technique is rather scarce compared to *ex situ* approach. Furthermore, the incorporation of hydrophilic silica gel with a monomer obscures polymerization process causing a reduction in membrane molecular weight and the formation of undesirable cross-linking (Mishra et al. 2012). Therefore, the fabrication of commercial composite membrane for fuel cell application such as Nafion[®] uses an *ex situ* approach due to its simplicity and controllability.

Silica membrane is a thin layer of silicon oxide consisting of microporous structure with pore size distribution of 0.3 nm (Lee et al. 2011). This feature enables small molecules such as hydrogen to pass through its microporous channels. Silica membrane is robust to be used at higher temperature and harsh conditions for longer operating period due to high melting point of silica. However, silica membrane will suffer an instability problem if it is used at higher temperature in the presence of water vapor due to the densification of silica (Saito et al. 2012). However, this problem

Silica Membrane,

Fig. 1 Silica membrane is normally grown on an intermediate layer to produce defect free-membrane

does not occur when silica membrane is used at lower temperature.

To enhance the performance of silica membrane, the membrane should be fabricated as thin as possible to reduce the pressure drop; thus, it requires a porous support to enhance its mechanical stability (Kumar and Gulians 2010). Figure 1 shows the alumina support with high porosity is used to maintain the structure of silica membrane. Prior to the growth of silica membrane, an intermediate layer is fabricated on top of the porous support to ensure a uniform intermediate layer can be provided. This approach is to avoid the formation of crack or pinhole that reduces silica performance.

Sol-gel method is the most common approach used for the fabricating silica membrane of a porous support due to its simplicity, controllability, and homogeneity (Koutsonikolas et al. 2011). However, this technique is unreliable to produce a defect-free membrane. On the other hand, chemical vapor deposition (CVD) is an alternative method to synthesize silica membrane on a porous support, but it tends to produce a silica membrane with high selectivity but lower permeance (Koutsonikolas et al. 2010). In the fabrication process, a method to enhance the durability toward water vapor should be emphasized when considering the silica membrane for practical uses (Saito et al. 2012). To enhance the durability of silica membrane, an additive can be used which is added at the beginning of preparation step (Lin et al. 2012; Tseng et al. 2011; Wang and Tsuru 2011; Araki et al. 2011). The silica-composite membrane has been tested and the results showed

that the composite membrane possesses stability when operated under hydrothermal conditions (Yang and Chen 2011). Another method to enhance the stability of silica membrane is through the incorporation and carbonization of covalently bonded templates into silica matrix (Lin et al. 2012; Vos et al. 1999). This approach limits the movement of silica in its matrix, thus improving hydrostability of the membrane.

Silica membrane has an advantage to be used for hydrogen purification process compared to palladium in terms of its economic point of view (Oda et al. 2010). The common application that uses silica membrane is a membrane reactor for hydrogen separation. Silica membrane is used to separate hydrogen from reaction zone, thus facilitating the equilibrium conversion toward product formation, which gives benefit to the performance of the membrane reactor. Silica membrane with higher selectivity and permeability can be used in other applications that require membrane reactor such as water-gas shift reaction, ethanol steam reforming, Haber process, and methane reforming.

Silica membrane has also been potentially employed for various chemical processes such as desalination process and pervaporation (Lin et al. 2012). In desalination process, the separation of salt from water is made based on small kinetic diameter of water which is 2.6 Å compared to Na^+ and Cl^- , which are 7.2 Å and 6.6 Å, respectively (Lin et al. 2012). In pervaporation application, the separation process is also taking advantage of small kinetic diameter of water. However, this process requires heat to turn the feed into vapor

phase, thus facilitating the separation process (Araki et al. 2011). Silica membrane can demonstrate an exceptional sustainability over a long period for the pervaporation application due to the high melting point of silica materials.

Silicalite Membrane

Tsuneji Sano

Department of Applied Chemistry, Hiroshima University, Graduate School of Engineering, Higashi-Hiroshima, Japan

Zeolites are a class of crystalline aluminosilicates with highly regular and open microporous structures. More than 200 types of zeolite frameworks have been identified by the Structure Commission of the International Zeolite Association. Zeolite membranes combine the great advantages of inorganic membranes, such as temperature stability and resistance against solvents, with the molecular sieving effect. Zeolite silicalite (MFI, where the three characters indicate the framework type) with Si/Al ratio of ∞ is well known as a hydrophobic zeolite. Figure 1 shows the framework structure of MFI zeolite (International Zeolite Association Web site 2013). There are two channel systems: a straight channel running to (010) with ten-membered ring openings of 5.3×5.6 Å and a sinusoidal channel parallel to the (100) with ten-membered ring openings of 5.1×5.5 Å.

Silicalite membrane was prepared as a self-standing polycrystalline film at first and was very fragile (Sano et al. 1991). Therefore, the silicalite membranes are crystallized on porous supports such as sintered stainless steel disc or

Silicalite Membrane, Fig. 1 Framework structure of silicalite (MFI) zeolite (IZA web. 2013)

alumina disc(tube) with an average pore diameter of $0.5 \sim 2 \mu\text{m}$. Colloidal silica is added to a stirred mixture of tetrapropylammonium bromide (TPABr) and sodium hydroxide in solution, to give a hydrogel with a composition of $0.1 \text{ TPABr} \cdot 0.05 \text{ Na}_2\text{O} \cdot \text{SiO}_2 \cdot 80\text{H}_2\text{O}$. The hydrogel is

transferred to a stainless steel autoclave and kept at 170°C for 48 h. The separation performances can be evaluated by pervaporation measurements using various aqueous alcohol solutions as a feed. Flux and separation factor $\alpha(\text{ROH}/\text{H}_2\text{O})$ are calculated from following equations:

$$\text{Flux (kg/m}^2\text{h)} = \frac{(\text{Weight of permeate, kg})}{(\text{Membrane area, m}^2) \times (\text{Permeation time, h})} \quad (1)$$

$$\text{Separation factor } \alpha(\text{ROH}/\text{H}_2\text{O}) = \frac{[\text{C}_{\text{ROH}}/\text{C}_{\text{H}_2\text{O}}]_{\text{Permeate}}}{[\text{C}_{\text{ROH}}/\text{C}_{\text{H}_2\text{O}}]_{\text{Feed}}} \quad (2)$$

where the C_{ROH} and $\text{C}_{\text{H}_2\text{O}}$ are the volume fractions of alcohols and water, respectively.

Figure 2 shows scanning electron micrographs (SEM) of the outer surface and cross-section of the membrane on the stainless steel support (Sano et al. 1994). The surface is formed of an aggregate of crystals of $10 \sim 30 \mu\text{m}$ and the growth on the support led to a randomly grown crystalline layer. The average thickness of the silicalite layer was confirmed by Si line analysis using energy-dispersive X-ray analysis (EDX). The organic amine used in the silicalite synthesis as a template remains in the channels of silicalite crystals. In order to use the membrane as the separation membrane, the amine must be removed from the

channels by certain procedures. As the silicalite membrane experiences the irregular stresses that arise from a difference in the thermal expansion between the support and the silicalite crystals or from removal of volatile materials from the zeolite framework, cracks are easily formed within the membrane during the treatment process. Therefore, pretreatment conditions of membranes affect strongly the separation performance. As listed in Table 1 (Sano et al. 1994), the silicalite membrane after air-drying at 100°C (containing TPA^+) shows a very low flux combined with a low separation factor below 1, indicating that there is no cracks and pores between silicalite grains within the membrane before the pretreatment. However,

Silicalite Membrane,

Silicalite Membrane, Table 1 Influence of pretreatment conditions on pervaporation performance of silicate membrane (Reproduced from Sano et al. (1994) with the permission of Elsevier)

Treatment condition			Flux (kg/m ² h)	Separation factor α (EtOH/H ₂ O)
Air-drying	100 °C	12 h	0.00303	0.38
In vacuum	300 °C	6 h	0.00840	0.58
In vacuum	380 °C	6 h	0.0394	7.8
Calcination	500 °C	20 h	0.760	58

Feed temperature: 60 °C

Feed ethanol concentration: 5 vol.%

Silicalite Membrane, Fig. 3 Pervaporation flux and separation factor α for various alcohol/water mixtures (Reproduced from Sano et al. (1994) with the permission of Elsevier). Feed alcohol concentration: 1 mol%

in the case of the membrane after the thermal treatment, the flux and the separation factor increase with an increase in the treatment temperature and period. The membrane calcined at 500 °C to remove the template completely shows the high flux combined with the higher separation factor. The membrane changes from the water-selective membrane to the ethanol-selective one by decreasing the amount of TPA⁺ occluded in the zeolite framework, and the separation of ethanol/water takes place by transport through the zeolite channels. Figure 3 displays effects of the feed temperature on the separation factor and the flux for various alcohol/water mixtures (Sano et al. 1994). The high separation factor

is obtained for 1-propanol/water mixture, although the flux is very low. On the other hand, the higher flux and the lower separation factor are obtained for methanol/water mixture. This can be explained by the differences in the molecular size and the interaction between alcohol and silicalite, methanol being the smallest and the most polar molecule in the group of alcohols tested here.

Silver Recovery by Bulk Liquid Membrane (BLM)

Pietro Argurio

Department of Environmental and Chemical Engineering, University of Calabria, Arcavacata di Rende, Italy

The occurrence of silver in the natural water environment is of great relevance owing to its toxicity to aquatic plants and animals even at very low concentration, particularly when it is in the free ion form (Ag^+). Silver content into the aquatic environment has increased in the last years owing to its increasing use in the medical and photographic-imaging industry and in the manufacturing of electronics, silverware, and jewelry. An estimated amount of 150 tons of silver is released into the aquatic environment every year. As a result, separation and recovery of silver from industrial wastewaters is of great importance (Altin et al. 2010).

Conventional separation process includes processes like solvent extraction, chemical precipitation, adsorption, and membrane filtration. These techniques efficiently remove metal ions producing water within international health standards, but present some limitations: (i) large amount of solvent required when dilute solutions were processed, making solvent extraction not very cheap and safe, since the used solvents are often chlorinated and sometimes carcinogenic; (ii) production of a large amount of toxic chemical

sludge in which disposal/treatment is a very costly affair and it is not eco-friendly; (iii) poor process selectivity, thus metal recovery is not achieved; (iv) adsorption-based processes are not continuous, requiring regeneration steps that negatively affect process economy.

Carrier-mediated transport through liquid membrane (LM) has been recently considered as one of the most powerful technology to concentrate, separate, and recover metal ions from diluted solutions. LM-based separation techniques combine extraction and stripping into a one-step process, thus having great potential for reducing the solvent inventory requirement and also allowing the use of expensive and highly selective extractant (Molinari and Argurio 2009). The lower capital and operating costs, the low energy consumed, and the high selectivity are the main advantages of LM systems. Thanks to these characteristics, LM-based techniques permit to obtain the recovery of heavy metal ions and the production of water with good quality, resulting into both environmental and economic benefits.

LM-based process includes bulk liquid membrane (BLM), emulsion liquid membrane (ELM), and supported liquid membrane (SLM). BLM usually consists of two aqueous phase (feed and strip) separated by a water-immiscible liquid membrane phase (Molinari and Argurio 2011). Usually the organic solvents, employed as LM phase, are pre-saturated with water by shaking a two-phase mixture and then removing the aqueous phase.

N,N-diethyl-N'-camphanyl thiourea is a very efficient carrier that showed very selective Ag (I) extraction and transport in the presence of Co (II), Ni(II), Cu(II), Zn(II), Cd(II), and Pb(II) using the pH gradient method (Berhe et al. 2006). The aqueous feed phase pH, higher than that one of the strip phase, is usually lower than 5 to avoid metal hydroxides precipitation. The strip phase usually consists of an acid (e.g., HNO_3) dissolved in deionized water. The main operating parameters affecting transport selectivity are the operating pH and the carrier/metal ratio. It was found that process selectivity decreases by increasing the carrier concentration in the LM phase.

Silver Recovery by Bulk Liquid Membrane (BLM), Fig. 1 Facilitated coupled cotransport for Ag(I) transfer across a liquid membrane

Macrocyclic ligands (e.g., crown) represent a promising class of complexing agents tested in the previous years in silver recovery by BLM (Rounaghi et al. 2008, 2011). In this case the Ag (I) is transported from the feed aqueous phase to the strip phase by the so-called facilitated coupled cotransport (Fig. 1). At feed-LM interface (Fig. 1), the carrier L extracts both Ag^+ ion and the counterion Cl^- by the reversible reaction (1):

The so formed complex diffuses through the membrane towards the stripping solution where the de-complexation reaction takes place, and Cl^- and Ag^+ ions are released. The so regenerated carrier molecule diffuses back to the feed, and the transport cycle begins again (Fig. 1).

Thiosulfate (Rounaghi et al. 2008), cyanide, or sulfite ions or other ligands can be used as stripping agent to improve the permeating flux. Ag^+ ions released in the strip phase react with the ligand to form a complex:

This reaction facilitates the release of Ag^+ ions from the LM phase into the strip phase that

usually is the rate determining step of the membrane transport. The permeating flux largely depends on the nature and concentration of the stripping ligand: for Ag^+ , recovery by BLM with dibenzopyridino-18-crown-6 and the presence of thiosulfate as stripping reagent in the strip phase caused an evident enhancement in transport efficiency.

Silylation

Catia Algieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In the 1970s, changing of the pore size of the zeolite silylation with SiH_4 was carried out (Barrer et al. 1977). In general, silylation technique permits the formation of a chemical bond between a chemical species containing silicon (e.g., SiH_4 and $\text{Si}(\text{OR})_4$) and both organic and

inorganic materials. The mechanism of these reactions is showed below.

Silylation is largely used to modify microporous, mesoporous, and nonporous inorganic particles (as zeolites, mesoporous, and nonporous silica materials). Besides, it was also used to cure the defects of both inorganic and mixed-matrix membranes. Some examples are reported below. Zheng and coworkers modified HZSM-5 crystals by silylation with tetraethoxysilane (Zheng et al. 2006). The modified crystals were used in xylene isomerization. Experimental results showed as silylation has significantly different effects on m-Xylene and o- and p-Xylene isomerization because of the inner pores that were hardly influenced. Recently, it was demonstrated the possibility to modify the surface of calcined MCM-41 by means of silylation (Patel et al. 2011). Nitrogen adsorption data and FTIR spectroscopy showed as the trimethylchlorosilane was chemically bonded to the surface of the inorganic material and not just physically adsorbed. Silylated MCM-41 preferentially adsorbed from benzene–water mixtures with a complete rejection of the water. MFI and SAPO-34 membranes were silylated with methyldiethoxysilane to improve their permeation properties (Hong et al. 2005). The results showed that as the chemical modification reduced the B-ZSM-5 pore size as a consequence, an increase of the hydrogen selectivity was detected. However, the hydrogen permeance decreased more than one order of magnitude. For example, H_2/CO_2 separation selectivity increased from 1.4 to 37 at 200 °C. For the SAPO-34 membranes, the results were different. In fact, the selectivity increased but the H_2 permeance remained the same. It is possible to explain these data considering that the methyldiethoxysilane did not enter into the

SAPO-34 pores. Recently, Hong and coworkers found, for ZSM-5 membrane, that the hydrogen selectivity increases while its permeance decreased (Hong et al. 2013). Mixed-matrix membranes (MMMs) are systems designed to improve the properties of a host polymeric matrix taking advantage of peculiar properties of the inorganic fillers (as zeolites). However, using glassy polymer, defects are present at the interface between the particle and polymer. Silylation process is used to modify the zeolite surface in order to compatibilise the inorganic filler with the host matrix (Vrancken et al. 1995). As an example, Clarizia and coworkers (2008) prepared MMMs by using unmodified and silylated (γ -aminopropyldiethoxymethylsilane) zeolite. Better permselectivity values were obtained with the MMMs prepared with modified crystals.

Simple Emulsion

Gemma Gutiérrez, María Matos and Carmen Pazos

Department of Chemical and Environmental Engineering, University of Oviedo, Oviedo, Spain

An emulsion is a two-phase system consisting of two immiscible liquids, one of which is in the shape of droplets dispersed in the second one. The liquid with droplet shape is referred to as *dispersed phase* or *inner phase*, while the liquid in which these droplets are suspended is called the *continuous phase* or the *external phase* (Morrison and Ross 2002).

In most cases, emulsions are inherently unstable because they have large interfacial/surface area and high interfacial/surface energy. Consequently, emulsions do not tend to form spontaneously, and energy must be supplied to the bulk phases to induce emulsification (Holmberg et al. 2002). Industrial emulsification processes mainly involve the use of high-pressure

homogenizers, rotor-stator devices, colloid mills, ultrasonic devices, and microfluidizers. Membrane emulsification is another technique used to prepare emulsions. This approach permits one to control the size of the droplets present in the emulsion (Joscelyne and Trägårdh 2000).

Several types of emulsions have been described (Tadros 1983). The most common consists of oil droplets (hydrophobic liquid) dispersed in an aqueous phase (hydrophilic liquid). These systems are referred to as oil-in-water (O/W) emulsions, whereas water droplets suspended in an organic phase are known as water-in-oil (W/O) emulsions.

The structure of an emulsion depends to a great extent on the volume fractions of water, oil, and a third component called *stabilizer*. There are several stabilizing agents, such as surfactants, proteins, polymers, or particles (Binks 2002), with surfactants being the most commonly used stabilizers. The type of emulsion (O/W or W/O) depends on surfactant properties, which should be soluble in the continuous phase (Bancroft 1913, 1915).

This empirical observation can be rationalized by considering the interfacial tension at the

Simple Emulsion, Fig. 1 Ternary phase diagram of an emulsion: *O* oil, *W* water, *S* surfactant

oil-surfactant and water-surfactant interfaces. W/O emulsions result when the volume fraction of water is low. By contrast O/W emulsions are formed when a small volume of oil is dispersed in a large amount of water. Moreover, for systems formulated with similar volume fractions of oil and water, a bicontinuous structure (liquid crystal) is likely to exist. A general ternary phase diagram of an emulsion is shown in Fig. 1.

Emulsions play an important role in the formulation of foods, pharmaceuticals, and cosmetic products because they offer a wide variety of applications as drug delivery carriers or encapsulation systems of bioactive compounds; however, emulsions are also used as metalworking fluids because they combine lubricating and cooling properties (Becher 1983).

Microemulsions are a special type of emulsion characterized by droplet sizes below 100 nm. Its appearance is translucent because light can traverse the emulsion without being scattered (Fanun 2008).

Sintering Method for Ceramic Membrane Preparation

Zhaoliang Cui

State Key Laboratory of Materials-Oriented Chemical Engineering, College of Chemistry and Chemical Engineering, Nanjing Tech University, Nanjing, China

Sintering method for ceramic membrane preparation. During ceramic membrane preparation, various shaping techniques such as slip/tape casting, extrusion, and pressing are used to make membrane precursors from particle suspension, slurry, or paste. No matter which process is adopted to prepare the ceramic membrane precursors, sintering (firing step) is necessary to yield the membranes promising mechanical strength and pore structure. When sintering process is conducted at high temperature, contact surfaces of the microparticles are partly sintered together. The final membrane pore structures, such as pore size, porosity, and tortuosity, are directly affected by the sintering parameters including temperature, pressure, particle size, and so on. Generally for the unsupported sintering, with the increase in sintering temperature, membrane pore size distribution becomes narrow, the mean pore size, maximum pore size, and porosity decrease. Moreover, a repeated sintering procedure can further fabricate multilayer membranes after coating step, such as dip-coating, sol–gel processes, and so on (Li 2007).

The price of ceramic membranes is high, so it is worthy to find the way to reduce its cost, which is very sensitive to sintering temperature, especially when they are used in water treatment (Cui et al. 2011). The cost sintering temperature for high purity alumina ranges between 1500 °C and 1700 °C. There are two general approaches to enhancing sintering kinetics or lowering the sintering temperature for ceramics. The first way is improving powder processing by using fine starting powders and eliminating agglomerates

such as by colloidal routes. The second approach is using sintering aids or additives (Xue and Chen 1991).

During the ceramic membrane preparations, constrained sintering, which involves the use of nonsintering layers, either porous or dense, to constrain the shrinkage in the layer plane, is worth to study. A model (Qiu et al. 2009) has been developed based on the sintering mechanism to calculate the change in the pore size and porosity of a ceramic membrane during sintering process. It was found that the porosity of the supported membrane is greater than the unsupported membrane at the same sintering temperature, thanks to the effect of the rigid substrate. As the sintering temperature increases, the mean pore size decreases for the unsupported membranes but increases for the supported membranes.

Sol–Gel Method for Ceramic Membrane Preparation

Zhaoliang Cui

State Key Laboratory of Materials-Oriented Chemical Engineering, College of Chemistry and Chemical Engineering, Nanjing Tech University, Nanjing, China

The sol–gel technique is commonly used to obtain the desired pore sizes in the top layer of ceramic membranes. Two main routes, colloidal route and polymer route, have been developed to prepare the sol–gel membranes. In the colloidal route, a metal salt is mixed with water to form a sol, which is coated on a membrane support, where it forms a colloidal gel; in the polymer route, metal–organic precursors are mixed with organic solvent to form a sol, which is then coated on a membrane support, where it forms a polymer gel (Li 2007). Polymeric sols have the potential to fabricate smaller pore sizes than particulate sols as the obtained gel layer is built up of a polymeric network (Lindqvist and Lidén 1997).

After drying the coated sol, gelation takes place. Then, the gel particles become sintered and the membranes are produced after thermal treatment. The sol–gel technique has an advantage that the membrane pore size can be controlled desirably, especially for small pores. So it is commonly used to prepare the desired pore sizes in the top layer. The pore size depends on the particle size in the sol. Very small particulate sols are required to obtain pores in the nanometer range (Leenaars et al. 1984).

Solid Electrolyte

Tanja Vidakovic-Koch

Max Planck Institute for Dynamics of Complex
Technical Systems, Magdeburg, Germany

Solid electrolytes (SE) also termed “superionic solids” or “fast ion conductors” are solid state ionic materials exhibiting an exceptionally high ionic conductivity, in the range of ionic conductivities of liquid/aqueous electrolytes (Agrawal and Pandey 2008). They found applications in different electrochemical systems, like batteries and fuel cells, since their use eliminates leakage problems associated with liquid electrolytes and improves system safety and durability. In electrochemical systems, (see “► [Electrochemical Processing](#)”) in addition to charge transport, solid electrolytes serve as separators, i.e., membranes as well.

In general, there are two classes of these materials: inorganic ceramics and organic polymers. In the case of ceramic solid electrolytes, the ionic conduction relies on movement of ionic point defects, which usually implies high ionic conductivity only at elevated temperatures. Examples of these materials utilizing O_2^- ion as a charge carrier are yttria stabilized zirconia (YSZ), scandia stabilized zirconia (ScSZ), as well as perovskite materials such as Sr/Mg-doped lanthan gallate (LSGM) (Sunmdacher et al. 2005). These materials have found an application in high temperature fuel cells and electrolyzers. In addition to oxygen ion conductors, proton conductors and Li-ion conductors are interesting for technical applications. The Li^+ ion conductors have importance for development of Li-ion batteries. Among these materials, $Li_{1+x}Al_xGe_{2-x}(PO_4)_3$ (LAGP) showed so far the best conductivity (Fergus).

Solid polymer electrolytes are an ion conducting membranes with ionic conductivity

above $10^{-7} \text{ S cm}^{-1}$ at room temperature (Agrawal and Pandey 2008). For technical applications conductivities higher than $10^{-4} \text{ S cm}^{-1}$ at room temperature, in addition to chemical and thermal stability, the capacity to be manufactured in thin-sheets and low permeability for reactants/products are favored. Solid polymer electrolytes can be roughly classified into three groups: dry solid polymer electrolytes, polymer gel electrolytes, and polyelectrolytes. In the first group, polymer itself serves as a solvent, solvating ionic salts into a polymer host. An example is poly(ethylene)oxide which is effective in solvating lithium salts for application in Li-ion batteries. In the second group, organic or inorganic liquid electrolyte is incorporated into the polymer matrix forming a polymer gel electrolyte. Example is poly(benzimidazole) doped with phosphoric acid, which found an application in high temperature fuel cells and poly(methyl methacrylate) (PMMA) and poly-acrylonitrile (PAN) cross-linked with lithium or sodium salts with applications in batteries. Third group makes so-called polyelectrolytes. They are macromolecules which upon placing into water or other ionizing solvent dissociate into highly charged polymeric molecules. An example is sulfonated tetrafluoroethylene based fluoropolymer-copolymer commercially (Nafion[®]) by DuPont which found an application in low temperature fuel cells and electrolyzers.

Solid Electrolyte Membrane Reactor

Tanja Vidakovic-Koch

Max Planck Institute for Dynamics of Complex
Technical Systems, Magdeburg, Germany

Solid electrolyte membrane reactor is a type of an electrochemical reactor which utilizes a solid electrolyte (an ion-conducting membrane) as an ion-conducting medium and a separator (Sundmacher et al. 2005). These reactors found an application in electrochemical processing. Examples are fuel cells, batteries, and electrolyzers. Electrochemical oxidation and reduction reactions in **solid electrolyte membrane reactor** take place in porous electrodes which are usually directly applied on different sides of the solid electrolyte. These electrodes are complex composite structures which have to fulfill different requirements. They should possess catalytic activity such that electrochemical reactions can take place; they should be able to conduct electrons and ions which are released or consumed in electrochemical reactions, and they should transport non-charged reactants or products of reactions to or away from the reaction site. In practice it is difficult to satisfy all these requirements. Currently so-called gas diffusion electrodes which found major application in fuel cells and electrolyzers show practically the best balance of mentioned requirements. Gas diffusion electrodes are usually prepared by mixing of a solid electrolyte, with an inert electron-conducting phase (e.g., carbon nanomaterials for low-temperature applications) and catalyst particles (e.g., platinum).

In fuel cells the main goal of operation is conversion of chemical energy of a fuel, typically hydrogen or hydrocarbons into electrical energy with high efficiency. Fuel cells work in a wide temperature range (25–1000 °C), for which different solid electrolytes (ceramics or polymers, see solid electrolytes) are used. Typical examples are solid oxide fuel cells which utilize ceramic oxygen ion-conducting membrane (e.g., yttria-stabilized zirconia) and polymer electrolyte fuel cell where polymer proton-conducting membrane (e.g., sulfonated

tetrafluoroethylene-based fluoropolymer-copolymer, commercially Nafion[®] by DuPont) is used.

Similar to fuel cells, in batteries the main goal of operation is efficient conversion of stored chemical energy into electrical energy. One example is lithium-ion polymer battery. This type of battery exhibits up to date the highest energy density of all batteries (380 Wh kg⁻¹) and allows a great variety of geometries as well as thicknesses of about 1 mm, which has found wide commercial application in cell phones and laptop computers.

Unlike electrochemical energy-conversion devices (fuel cells and batteries), the main purpose of electrolyzers is high production rate of a specific product at high selectivity and low energy consumption. In some cases the desired product and electrical power can be cogenerated. A detailed survey of applications of high-temperature solid electrolyte membrane reactors for production of different industrially relevant products is presented in Garagounis et al. 2011. Although in some cases notable advantages of solid electrolyte membrane reactors in comparison to conventional catalytic reactor have been identified, this technology still did not reach commercial stage.

Solid Lipid Particles

Emma Piacentini

Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Solid lipid particles represent an alternative carrier system to traditional colloidal carriers, such as emulsions, liposomes, and polymeric micro- and

Solid Lipid Particles, Table 1 Methods of preparation of solid lipid particles

Method	Description	Advantages/disadvantages
Emulsification + cooling		
Hot	The lipid is melted at approximately 5–10 °C above its melting point and dispersed under stirring in a hot aqueous surfactant solution of identical temperature. The produced hot O/W emulsion is cooled down to room temperature; the lipid recrystallizes and leads to solid lipid particles	Temperature-induced drug degradation, drug distribution into the aqueous phase during homogenization, complexity of the crystallization step of the nanoemulsion leading to several modifications and/or supercooled melts
Cold	The melt lipid is cooled and the solid lipid ground to lipid microparticles that are dispersed in a cold surfactant solution yielding a pre-suspension. Then this pre-suspension is homogenized at or below room temperature to break in smaller solid lipid particles, the lipid microparticles. The difference between the melting point of the lipid and the homogenization temperature needs to be large enough to avoid melting of the lipid in the homogenizer	Avoid or minimize the melting of the lipid minimizing loss of hydrophilic drugs to the water phase
Emulsification + solvent evaporation	The lipid is dissolved in an organic solvent and the solution is emulsified in an aqueous phase. After evaporation of the organic solvent, the lipid will be precipitated forming solid particles	The use of pollutant organic solvents

nanoparticles. A solid lipid is used instead of a liquid oil as dispersed phase. The term lipid includes triglycerides (e.g., tristearin), diglycerides (e.g., glycerol behenate), monoglycerides (e.g., glycerol monostearate), fatty acids (e.g., stearic acid), steroids (e.g., cholesterol), and waxes (e.g., cetyl palmitate).

The most used methods of preparation of solid lipid particles are listed in Table 1. The emulsification step can be carried out using the conventional mechanical methods or by membrane emulsifications. The selection of the most suitable method depends on the properties of the lipid and the drug incorporated.

Advantages of solid lipid particles include the composition (physiological compounds), the rapid and effective production process including the possibility of large-scale production, and the possibility to produce carriers with higher encapsulation efficiency. Disadvantages include low drug-loading capacities, the complexity of the physical state of the lipid (transformation between different modifications), and the possibility of supercooled melts which cause stability

problems during storage or administration (gelation, particle size increase, drug expulsion). Solid lipid particles are one of the novel potential colloidal carrier systems as alternative materials to polymers. They have many advantages such as good biocompatibility and low toxicity, and lipophilic drugs are better delivered by solid lipid particles, and the system is physically stable. Other advantages of solid lipid particles include: control and/or target drug release, improved stability of pharmaceuticals, high and enhanced drug content, better control over release kinetics of encapsulated compounds, enhanced bioavailability of entrapped bioactive compounds, chemical protection of labile incorporated compounds, much easier to manufacture than biopolymeric nanoparticles, and very high long-term stability.

Three drug incorporation models can be considered:

1. Solid solution model. The solid lipid particles matrix is a solid solution (containing the drug dispersed in the lipid matrix) when the particles

Solid Lipid Particles,

Fig. 1 Three drug incorporation models (solid solution model, core-shell models with drug-enriched shell, and drug-enriched core)

are by cold emulsification + cooling and using no surfactant or no drug-solubilizing surfactant (Fig. 1a).

2. Core-shell model, drug-enriched shell. A drug-enriched shell is obtained when the drug precipitates first before the lipid recrystallizes. This should be obtained when dissolving a drug in the lipid melt at or close to its saturation solubility. Cooling of the emulsion leads to a supersaturation of drug in the melted lipid and subsequently to drug crystallization prior to lipid crystallization (Fig. 1b).
3. Core-shell model, drug-enriched core. Further cooling will finally lead to the recrystallization of the lipid surrounding the drug core as a membrane. This lipid membrane will contain only drug in such a concentration corresponding to the saturation solubility of the drug at the recrystallization temperature of the lipid. That means it will result in a drug-enriched core surrounded by a lipid shell (Fig. 1c).

Solid lipid particles have been introduced as a novel drug delivery system for pharmaceutical drugs in various application routes (Müller et al. 2000). They also represent a promising carrier system for cosmetic active ingredients due to their numerous advantages over existing conventional formulations (Müller and Dingler 1998). Solid lipid particles have potential multiple applications in the food and agricultural industries (Weiss et al. 2008). They are of particular interest to manufacturers of functional foods that are looking for novel ways to include lipophilic but chemically sensitive bioactive compounds.

Solubility

Maria Grazia De Angelis
Dipartimento di Ingegneria Civile, Chimica,
Ambientale e dei Materiali, Università di
Bologna, Bologna, Italy

Solubility (*C*) is a thermodynamic quantity characterizing the distribution of chemical species between different phases in equilibrium. In particular, the solubility (of a *solute* in a *solvent*) expresses the amount of chemical species (*solute*), dissolved in a fixed amount of an uptaking species (*solvent*), at equilibrium. The equilibrium is reached at the end of a *sorption* (or *absorption*) process, in which the solute molecules spontaneously move from the original phase to the solvent phase and form a homogenous mixture (solution) of molecules interacting with noncovalent bonds. Often the

term “solubility” is also used to indicate the sorption process.

The solubility value is measured when the solute net mass transfer is zero and an equal chemical potential of the solute species in the two phases is attained. The time required to reach such equilibrium state depends on the diffusivity of the solute in the solvent in the state of the solution, on the geometry of the system, and the boundary and initial conditions of the mass transfer problem. The solubility of a solute in a solvent depends on the respective chemical nature and thermodynamic state but also on binary interactions and can be obtained by solving the phase equilibrium problem, with an appropriate model that allows to represent the chemical potential.

The solubility is thus a measure of solute concentration at equilibrium and can be expressed in mass, molar, or volume terms and using different units as reported in Table 1.

In membrane processes governed by the solution-diffusion framework like gas and vapor separation, pervaporation, and liquid/liquid separation, the membrane is the solvent in equilibrium with the feed and permeate fluid phases on the upstream and downstream side, respectively. The concentration of solute i absorbed onto the membrane boundaries is equal to $C_{i,\text{up}}$ and $C_{i,\text{down}}$, respectively. The difference $\Delta C_i = C_{i,\text{up}} - C_{i,\text{down}}$ ensures solute mass flux across the membrane, according to Fick's law.

Solubility can be measured via gravimetric, manometric, optical methods, etc. (Czichos

et al. 2006) and is usually expressed through curves (solubility isotherms) reporting isothermal data.

According to the phase rule, in the system formed by two phases (the original solute phase and the solvent phase), one solvent and N_S solute species, the number of variables required to univocally define the state of the system is N_S+1 .

The solubility isotherm of a solute i in a solvent reports the solubility of that solute in the solvent versus the composition of the solute in the original solute phase, which can be expressed with different quantities depending on the state of aggregation of such phase. Some examples are given below.

For a *gaseous* solute phase, the *fugacity* f_i or the *partial pressure* p_i , if the gas phase is ideal, is used.

For a *vapor* solute phase, the activity (a_i) is preferentially used, i.e., the ratio between the *fugacity* in the current state and the fugacity in a reference state, that is usually chosen to be the vapor/liquid saturation point of the pure solute at the same temperature:

$$a_i = \frac{f_i(T, p, y_i)}{f_i^0(T, p_{i,\text{SAT}}(T))} \xrightarrow[\text{pressure}]{\text{low}} \frac{py_i}{p_{i,\text{SAT}}(T)} \quad (1)$$

For *pure liquid solute phases*, the solubility, as many other liquid-state properties, is to all practical purposes a weak function of pressure, and its value can be assumed unique at a fixed temperature.

For *multicomponent liquid solute phases*, the activity a_i can be used, being γ_i the activity coefficient:

$$a_i = x_i \gamma_i^{\text{ideal}} \equiv x_i^{\text{mixture}} \quad (2)$$

Solubility and Partitioning

Maria Grazia De Angelis
Dipartimento di Ingegneria Civile, Chimica,
Ambientale e dei Materiali, Università di
Bologna, Bologna, Italy

When a solute is added to two immiscible (or partially miscible) phases, it will distribute unevenly between them, giving rise to the so-called solute partitioning between the phases. The distribution of a solute among coexisting phases, in particular liquid phases, is a phenomenon of industrial importance in several purification processes such as liquid extraction, partition chromatography, etc.

In membrane processes the partitioning occurs between the fluid phase (feed, permeate) and the membrane phase.

Partitioning of the solute i between the solute (I) and membrane (II) phase can be defined with the partition or distribution coefficient $K_{i,I/II}$ defined as the ratio between the concentration (solubility) of solute in the membrane phase and the concentration (solubility) of solute in the external phase, that is normally lower than unity:

$$K_{i,I/II} = \frac{C_{i,I}}{C_{i,II}}$$

Partition coefficient of solute i between phase I and phase II.

Solubility Coefficient (S)

Maria Grazia De Angelis
Dipartimento di Ingegneria Civile, Chimica,
Ambientale e dei Materiali, Università di
Bologna, Bologna, Italy

The solubility coefficient, S_i , of a gas i in a membrane is the ratio between its solubility C_i in the

membrane and its fugacity f_i or partial pressure p_i in the gas phase at constant temperature:

$$S_i = \frac{C_i}{f_i} \quad (1)$$

For gas sorption in polymer membranes, a common unit is $\text{cm}^3(\text{STP})/(\text{cm}^3(\text{pol}) \text{ atm})$. The solubility coefficient of a low-pressure gas in a liquid is the reciprocal of Henry's law coefficient H .

In the case of gas sorption in polymer membranes, of particular interest is the *infinite dilution solubility coefficient*, S_0 , that is evaluated in the limit of infinite dilution or zero pressure of penetrant in the gaseous phase.

$$S_{i0} = \lim_{p \rightarrow 0} \frac{C_i}{f_i} = \lim_{p \rightarrow 0} \frac{C_i}{p_i} \quad (2)$$

For vapor solubility in polymer membranes, the activity-based solubility coefficient is sometimes also used, $S_i p_{SAT}$, that is the ratio between solubility and corresponding penetrant activity, if the vapor phase is ideal.

The solubility coefficient at fixed fugacity represents the slope of the straight line connecting a point on the solubility isotherm to the origin (See Fig. 1b); S_0 is the slope of the tangent to the gas solubility isotherm in the zero-pressure limit (see Fig. 1a).

In the solution diffusion transport of solute i through membranes, Fick's law holds true for the gas flux inside the membrane at steady state:

$$J_i = D_i \frac{\Delta C_i}{l} \quad (3)$$

On the other hand, the permeability of gases in membranes is defined with respect to the pressure gradient of penetrant i , in steady state:

$$J_i = P_i \frac{\Delta f_i}{l} \quad (4)$$

Therefore, one has that

Solubility Coefficient (S), Fig. 1 Graphical determination of the solubility coefficient from the solubility isotherm: (a) infinite dilution solubility coefficient, (b) solubility coefficient, (c) average solubility coefficient

$$\begin{aligned}
 D_i \frac{C_{i,up} - C_{i,down}}{l} &= P_i \frac{f_{i,up} - f_{i,down}}{l} \rightarrow P_i \\
 &= D_i \frac{C_{i,up} - C_{i,down}}{f_{i,up} - f_{i,down}} \equiv D_i S_{i,AVE}
 \end{aligned}
 \quad (5)$$

where $S_{i,AVE}$ is the slope of the straight line connecting the upstream and downstream points on the solubility isotherm (see Fig. 1c). In the figure, the case of a concave down solubility isotherm has been taken as an example to represent the graphical meaning of S (here and in the following the pedix i is omitted for simplicity sake).

Correlations for the Solubility Coefficient

The sorption of a gas in a membrane requires condensation of the gas, followed by mixing with the membrane molecules. Therefore, the higher the condensability of the membrane and its compatibility with the membrane material, the larger its solubility in the membrane at fixed temperature. A convenient measure of the penetrant condensability is the critical temperature, and empirical correlations of the following kind have been proposed in the literature for data relative to an homologous set of penetrants in a given polymer at fixed temperature (Bondar et al. 1999; Stern et al. 1969):

Solubility Coefficient (S), Table 1 Experimental and predicted values of correlation coefficients for the solubility coefficient of gases in glassy membranes (De Angelis et al. 2007)

	$\ln(S_0) = a + bT_C, \quad S_0 \text{ in } \text{cm}^3_{\text{gas}}(STP)/(\text{cm}^3_{\text{pol}}\text{atm})$			
	Experimental value		Predicted, NELF model	
35 °C	<i>a</i>	<i>b</i>	<i>a</i>	<i>b</i>
PC	0.0192	−4.0994	0.0226	−5.0123
PSf	0.0209	−4.2394	0.0215	−4.5165
PPO	0.0238	−3.6305	0.0242	−4.0788
PMMA	0.0212	−5.0132	0.0219	−4.8131

Solubility Coefficient (S), Fig. 2 Solubility coefficient of gases in: (a) rubbery PDMS membrane – fluorocarbon penetrants follow a different trend with respect to the other ones due to lower solubility (Adapted from De Angelis

et al. 1999). (b) Activity-based solubility coefficient of vapors in membranes can follow different trends with the vapor critical temperature: increasing, constant, or decreasing (Adapted from Galizia et al. 2012)

$$\ln(S_0) = a + bT_C \text{ at constant temperature} \quad (6)$$

$$\ln(S_0) = a' + b'T_C^2 \text{ at constant temperature} \quad (7)$$

$$\ln(S_0) = M + N(T_C/T)^2 \quad (8)$$

For rubbery polymers, the above correlation can be retrieved using Flory-Huggins theory and a few assumptions (Gee 1947). For glassy polymers, the correlation can be reproduced efficiently by the NELF model (De Angelis et al. 2007), as it can be seen in Table 1.

Other authors correlate the values of S_0 to other condensability-related parameters, such as the Lennard-Jones parameter (Van Krevelen 1990), critical volume, surface area (Yampolskii

et al. 2000), etc. It must be noticed that, when different series of penetrants are considered, the solubility data may fall on separate correlating lines. This is the case of fluorocarbon penetrants in PDMS which show lower solubility than the other gases of similar critical temperature, due to lower interaction with the polymer (De Angelis et al. 1999) (Fig. 2a).

The activity-based solubility coefficient of gases can increase or decrease with critical temperature (Galizia et al. 2012) (see Fig. 2b) because, being normalized for the different condensability of penetrants, accounts only for the mixing effects, which can be positive or negative depending on the gas-polymer interactions.

Solubility Coefficient (S),

Fig. 3 Solubility coefficient at infinite dilution of CO₂ in PC as a function of reciprocal temperature. Model results are also reported: SAFT equation-of-state and nonequilibrium SAFT model (Adapted from Giacinti et al. 2005)

**Dependence on Temperature**

The sorption of a gas or vapor into a solid membrane is usually an exothermic process in which the most important thermal effect is the negative heat of condensation of the fluid in the membrane phase. In addition, there is a mixing term which can be positive or negative depending on the solute-membrane couple, but is usually lower, in absolute value, than the condensation term.

Therefore, the solubility coefficient values for gases and vapors in polymer membranes decrease with temperature, usually according to an Arrhenius type of dependence, as follows:

$$S = S(T_0) \exp\left(-\frac{\Delta H_S}{RT}\right) \quad (9)$$

The heat of sorption assumes a different value for the rubbery and glassy state; in particular the higher value is observed in the glassy phase of the same amorphous polymer. This behavior can be seen, for instance, by reporting S_0 values as a function of $1/T$ (Fig. 3): the change of slope occurs at the membrane glass transition temperature.

For liquid solutes, there is no condensation term and the thermal effect associated to sorption in the membrane can be positive or negative.

Solubility of Gases in Membranes

Maria Grazia De Angelis
Dipartimento di Ingegneria Civile, Chimica,
Ambientale e dei Materiali, Università di
Bologna, Bologna, Italy

The solubility of gases in membranes directly affects the gas separation performance in processes governed by the solution-diffusion mechanism. Gaseous solutes (penetrants) are absorbed onto the upstream membrane side, diffuse through the membrane, and desorb from the membrane in the downstream side toward the permeate gas phase. According to Fick's law, in steady state, the flux of penetrant i through the membrane is associated with the diffusivity and concentration gradient $\Delta C_i/l$ as follows:

$$J_i = D_i \frac{\Delta C_i}{l} \text{ (steady state)} \quad (1)$$

Amorphous Rubbery Membranes

In polymer membranes above their glass transition point (*rubbery*), the solubility has a unique value once the temperature and penetrant fugacities are fixed. The solubility isotherms of gases in rubbers are linear, for light gases, or concave up for non-light gases and vapors (Fig. 1i). High-pressure gases (e.g., supercritical CO₂) are shown to exhibit a decrease of slope of the solubility isotherms at pressures above the critical one; in such range the fluid behavior resembles the liquid one, in which the properties vary slightly with the pressure (Fig. 1ii).

If the rubbery polymer is cross-linked, the swelling of the rubbery matrix and the solubility are lower than those measured in the uncross-linked rubber; indeed cross-linking can prevent

plasticization of the membrane by highly soluble vapors. The solubility of gases in rubbery membranes can be estimated with the Flory-Huggins and related activity coefficient models or with equation of state models (lattice fluid, SAFT, PHSC, etc.) (De Angelis and Sarti 2011).

Amorphous Glassy Membranes

Membranes below their glass transition point (*glassy*) are not at equilibrium due to the hindered mobility of polymeric chains, and the properties, including the solubility, can vary with time, either because of aging or as a consequence of thermal, mechanical, and chemical treatments. The state of the glassy membrane has to be defined with a proper parameter, such as the glassy membrane density, or equivalently the fractional free volume, in addition to the other state variables.

The solubility isotherms of gases in glassy membranes are linear for light gases or concave down for other gases and vapors (Fig. 1i). Some vapors (e.g., alcohols) in certain glassy polymers can show a sigmoidal shape of the solubility isotherm (Fig. 1iii).

If the glassy membrane is close to its glass transition temperature and/or if the penetrant has high solubility in the membrane and is able to significantly swell and plasticize the membrane, a glass transition can be observed at constant temperature by increasing the gas pressure (*sorption-induced glass transition*), which occurs as a change of concavity of the solubility isotherm (Fig. 1iv). The solubility in glassy membranes can be modeled by the dual mode empirical model (Barrer et al. 1958) or the nonequilibrium approaches proposed by Doghieri and coworkers (Doghieri and Sarti 1996, De Angelis and Sarti 2011).

Semicrystalline Membranes

The crystalline phase is considered impermeable and insoluble, and the solubility of the matrix is given by

Solubility of Gases in Membranes, Fig. 1 Different shapes of solubility isotherms in polymeric membranes. (i) (a) Sorption of gases and vapors in glassy membranes, (b) sorption of light gases in glassy and rubbery membranes, and (c) sorption of gases and vapors in rubbery membranes. (ii) Supercritical sorption in rubbery

membranes (e.g., CO₂ in PDMS), (iii) sigmoidal sorption of polar vapors in hydrocarbon glassy membranes (e.g., alcohols in PTMSP) (Nakanishi et al. 1987), and (iv) CO₂ sorption in an initially glassy membrane (e.g., PMMA) (Carlà et al. 2005)

$$C_i = (1 - \phi_{CR})C_{i,AM} \quad (2)$$

where ϕ_{CR} is the fraction of crystalline phase and $C_{i,AM}$ is the solubility in the amorphous phase. In some cases, however, the presence of the crystalline phase may vary the amorphous phase properties with respect to the pure state ones. In particular, it can reduce the specific

volume or reduce the ability of the matrix to swell, with a consequent lower solubility of the amorphous phase with respect to the pure phase: such phenomenon has been modeled invoking an additional pressure term, using both molecular and equation of state methods (Memari et al. 2010, Minelli and Angelis 2014).

Composite (Mixed Matrix) Membranes

In mixed matrix membranes, the solubility C_i of a fluid in a mixed matrix membrane (MMM) can be estimated with an additive rule based on the polymer (P) and filler (F) fractions in the MMM, and the solubility values in the corresponding pure phases, $C_{i,P}$ and $C_{i,F}$:

$$C_i = \phi_P C_{i,P} + (1 - \phi_P) C_{i,F} \quad (3)$$

However, in many cases, a deviation from this rule is observed. The filler phase, if porous, can be obstructed by contact with the polymer and its sorption capacity lowered. The imperfect adhesion between polymer and filler phase can modify the morphology and properties of the polymeric phase and its sorption capacity, as in the case of mixed matrices formed by glassy polymers and nanometric silica. In such systems the solubility increases, due to an increased free volume of the polymer (De Angelis and Sarti 2012).

Solubility Parameter

Maria Grazia De Angelis
Dipartimento di Ingegneria Civile, Chimica,
Ambientale e dei Materiali, Università di
Bologna, Bologna, Italy

The ► **solubility parameter** δ is a thermodynamic quantity introduced by Hildebrand and Scatchard (HS) to describe the behavior of the so-called regular solutions. Such solutions have a negligible mixing volume and excess entropy of mixing, so that the excess Gibbs free energy coincides with the mixing enthalpy. The HS model uses the idea of cohesive energy density (CED), that is, the difference between the internal energy of the system and that of the corresponding system in the ideal gas state, per volume of liquid substance, estimated as follows: (Sandler 2006)

$$\begin{aligned} CED &= \frac{(\Delta \tilde{U}_{VAP})_{L \rightarrow IG}}{\tilde{V}_L} \\ &= \frac{(\Delta \tilde{H}_{VAP})_{L \rightarrow IG} - RT}{\tilde{V}_L} \end{aligned} \quad (1)$$

And the solubility parameter δ is defined as:

$$\delta \equiv \sqrt{CED} \quad (2)$$

The solubility parameter is related to the molar excess Gibbs free energy, $\tilde{G}^{EX}$, and to the mixing enthalpy, $\Delta \tilde{H}_{MIX}$, by the following expression valid for a binary mixture:

$$\begin{aligned} \tilde{G}^{EX} &= \Phi_1 \Phi_2 (x_1 \tilde{V}_1 + x_2 \tilde{V}_2) (\delta_1 - \delta_2)^2 \\ &= \Delta \tilde{H}_{MIX} \end{aligned} \quad (3)$$

where:

$$\Phi_i = \frac{x_i \tilde{V}_i}{x_1 \tilde{V}_1 + x_2 \tilde{V}_2} \quad (4)$$

And for the activity coefficient of species i :

$$RT \ln \gamma_i = \tilde{V}_i \Phi_j^2 [\delta_i - \delta_j]^2 \quad (5)$$

The model is predictive for the solubility as far as the δ values of the two species are known and the theory can depict correctly the physical behavior of the mixture; indeed the equilibrium composition or solubility can be found applying the phase equilibrium condition for the solute species.

Although the HS theory is not always appropriate, especially for solutions containing polymers, as it does not account for mixing volume and excess entropy of mixing, and it uses the geometric mean rule assumption for the binary interactions between unlike molecules, the δ value is widely used to estimate a priori the mutual solubility of two species. Two species with similar δ values show little excess free energy and are mutually soluble in the entire composition range. Two components with dissimilar solubility parameters have high values of the excess free energy and can show a miscibility gap.

In gas sorption in membrane systems the values of solubility is higher if the gas and polymer solubility parameters are similar, and lower if they are dissimilar, at fixed condensability of the gaseous penetrant.

In some cases, it is evident that the solubility of different fluids in a membrane is strongly correlated to the solubility parameter difference.

Normally δ values are tabulated at 25 °C and their value is almost constant with temperature. For fluids, the values are easily retrievable. For polymers, the vaporization quantities cannot be measured, and the δ values can be estimated from experimental mixing data or with group contribution methods like the ones by Hoftyzer and Van Krevelen and by Hoy (Van Krevelen 1990). In both methods the same assumption is made that the cohesive energy is not only represented by the dispersion interaction forces between molecules, as originally assumed by the HS theory, but it accounts also for the polar groups interactions and for the hydrogen bonds:

$$CED = CED_D + CED_P + CED_H \quad (6)$$

And correspondingly:

$$\delta^2 = \delta_D^2 + \delta_P^2 + \delta_H^2 \quad (7)$$

Some values of the solubility parameters for polymers of interest in membrane separations, as measured

Solubility Parameter, Table 1 Solubility parameter values for some polymers

Polymer	δ (J ^{1/2} /cm ^{3/2}), experimental from mixing data	δ (J ^{1/2} /cm ^{3/2}), estimated with group contribution methods
Polyethylene	15.8–17.1	16.0
Polypropylene	16.8–18.8	17.0
Polyisobutylene	16–16.6	16.4

Solubility-Selective Membrane

Maria Grazia De Angelis
Dipartimento di Ingegneria Civile, Chimica,
Ambientale e dei Materiali, Università di
Bologna, Bologna, Italy

This term usually refers to polymeric membranes used for gas separation process and indicates those membranes whose selectivity is governed

by the solubility, rather than diffusivity, of the penetrants in the membrane. Indeed in gas separation with polymeric membranes, the selectivity α is the product of a solubility-selectivity, α_S , and of a diffusivity-selectivity term, α_D , according to the solution-diffusion model. It is generally thought that smaller penetrants are more permeable than large ones in solids due to the large diffusivity differences between small and large penetrants, but this trend, although very common, is not always valid.

In the solubility-selective membrane, some large, condensable penetrants are more permeable than the small, poorly condensable penetrants, due to their higher solubility and despite their lower diffusivity. This type of membranes is sometimes also called “vapor selective” or “reverse selective” as opposed to the “size-selective” ones, because vapors are usually more permeable than gases. Some rubbery polymers used in gas separation follow this trend, as, for instance, the polydimethylsiloxane (PDMS). In glassy polymers, the solubility-selective behavior is preferentially shown by those polymers characterized by rather large free volume, i.e., higher than around 15 % (polytrimethylsilyl propyne (PTMSP), poly(4-methyl-2-pentyne) (PMP), etc.) In those polymers, the diffusivity is a weakly decreasing function of the penetrant size, and thus the diffusivity-selectivity between small and large penetrants has limited values. On the other hand, the solubility is a strongly increasing function of the penetrant size or condensability; thus, for a couple of penetrants A and B, where A is larger than B, one can have that

$$\begin{aligned} \alpha_{S,A/B} &\gg 1 & \alpha_{D,A/B} &\leq 1 \\ \rightarrow \alpha_{S,A/B} &> (\alpha_{D,A/B})^{-1} & \rightarrow \alpha_{A/B} &= \alpha_{S,A/B} \cdot \alpha_{D,A/B} > 1 \end{aligned}$$

The permeability of different gases versus their size is reported in Fig. 1 for three types of polymer membranes: a solubility-selective one (PTMSP), a slightly diffusivity-selective one (amorphous Teflon® AF2400), and a strongly diffusivity-selective one (polysulfone, PSf). The permeability and selectivity values of some

Solute Reverse Transport

Saren Qi¹ and Chuyang Y. Tang²

¹Singapore Membrane Technology Centre, Nanyang Technological University, Singapore, Singapore

²Department of Civil Engineering, The University of Hong Kong, Hong Kong, Hong Kong SAR

Solute reverse transport refers to the diffusion of solutes from a high-concentration draw solution (DS) to a low-concentration feed solution (FS) in forward osmosis (FO) and pressure retarded osmosis (PRO). For an ideal semipermeable membrane with 100 % solute rejection, draw solutes are perfectly rejected such that there is no solute reverse transport. Real membranes do not have perfect rejections against solutes. Under a concentration gradient across the FO, the solutes diffuse from DS to FS. Because this draw solute flux is opposite to the direction of water flux, it is named as (draw) solute reverse flux. Solute reverse transport can lead to various negative impacts. In FO and PRO processes, draw solutes diffused to the FS reduce the DS concentration. The replenishment of draw solutes can significantly increase the operational cost. Additionally, draw solutes transported into feed solution side may induce severe internal concentration polarization (ICP) and therefore reduce the FO water flux (Zou et al. 2011). Certain types of draw solutes, once diffused into the FS, may interact with contaminants in the FS (e.g., Ca^{2+} from the DS can interact with foulants in the FS to induce the severe membrane fouling). Therefore, understanding and controlling the solute reverse transport is critical for more efficient FO and PRO operations.

In FO, the reverse solute flux (J_s) and water flux (J_v) can be mathematically expressed with the following equations (Tang et al. 2010):

$$J_s = B\Delta C = B(C_{\text{draw}} - C_{\text{feed}}) \quad (1)$$

$$J_v = A\Delta\pi = A(\pi_{\text{draw}} - \pi_{\text{feed}}) \quad (2)$$

where C_{draw} and C_{feed} are the concentration of draw solution and feed solution, respectively. π_{draw} and π_{feed} are the osmotic pressure of draw solution and feed solution, respectively. A is the water permeability of membrane and B is the solute permeability of membrane. The values of A and B can be determined by reverse osmosis testing. Substituting the Van't Hoff equation into Eqs. 1 and 2, one can get the relationship between J_s and J_v :

$$J_s = \frac{B}{A\beta R_g T} J_v \quad (3)$$

where β is the Van't Hoff coefficient, R_g is the universal gas constant, and T is the absolute temperature. From Eq. 3, we noticed that J_s is strongly influenced by B/A , which is an indicator of the membrane selectivity.

The reverse solute flux in PRO process is given by She et al. (2012)

$$J_s = \frac{B}{A\beta R_g T} J_v \left(1 + \frac{A\Delta P}{J_v} \right) \quad (3)$$

where ΔP is the transmembrane pressure difference.

Because of the high pressure used in PRO and the PRO membrane is generally not well supported by spacers, mechanical stress in the membrane tend to deteriorate the membrane rejection under PRO operation. Thus, the reverse solute flux tends to be much high in PRO compared to that in FO.

Solution-Diffusion Mechanism

► Principle of Gas Separation

Solvent Evaporation Membrane Crystallization

Gianluca Di Profio

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Solvent evaporation membrane crystallization is a membrane-assisted crystallization configuration where the substances to be crystallized are dissolved in an undersaturated solution located at the feed side of the membrane. In the current general conception, a nonvolatile solute that is likely to be crystallized (defined as the crystallizing solution or feed or retentate) is contacted, by means of a (macro)porous membrane, with a solution on the distillate side. The membrane might be made by polymeric or inorganic materials or by a combination of both in a hybrid or composite configuration. Hollow fibers as well as flat sheet membranes can be employed indifferently.

When the membrane is prevented to be wet from the adjacent solutions, no mass transfer through its porous structure is observed directly in liquid phase but the two contacted subsystems are subjected to mass inter-exchange in vapor phase. Wetting of the membrane, with the consequent deleterious direct passage of liquids, can be avoided when the pressure of the solutions facing it is lower than the entry limit (P_{entry}), defined by Young-Laplace's equation (Atkins 1998). This means that hydrophobic membranes can be used for hydrophilic (aqueous) crystallizing solutions and hydrophilic membrane materials are suitable for hydrophobic (or oleophilic) solutions.

For a pressure lower than P_{entry} , the two liquids are stopped at the entrance of each pore on both membrane sides, thus generating a curved profile. Crystal nucleation and growth in the feed solution

are induced by generating supersaturation. This can be done either by removing the solvent from the crystallizing solution, thus increasing solute concentration up to the overcoming of its solubility limit. Accordingly, the role of the membrane is not simply as a sieving barrier to select the transport of specific components but instead as a physical support which, by removal of the vaporized solvent or by addition of the antisolvent, generates and sustains a controlled supersaturated environment in which crystals can nucleate and grow.

The driving force for the mass transport of a component from one phase to the other is given by the difference in its electrochemical potential in the two phases, and it is generated by changes in temperature, pressure, activity, or electrical potential. The hydrostatic pressure gradient across the membrane is negligible in MCr to avoid wetting while the electrical gradient does not hold, so that the driving force of the process is the partial pressure difference across the membrane, established by a temperature or activity difference between the two contacted solutions. In the case of a driving force generated by a temperature gradient, the system is named thermal membrane crystallizer; when the driving force is obtained by an activity gradient, generated by a difference in ionic strength, the system is named osmotic (or isothermal) membrane crystallizer.

Under the action of the driving force, solvent molecules migrate, in vapor phase through the porous membrane structure, from the site where their chemical potential is higher toward the lower chemical potential subsystem, thus generating supersaturation and, hence, nucleation and crystal growth in the crystallizing solution. The specific mechanism for mass transport depends on the operational configuration of the membrane crystallizer. Two cases exist: (1) solvent evaporation membrane crystallizer (thermal or isothermal) in which solvent is removed in vapor phase from the crystallizing solution and (2) antisolvent membrane crystallizer where an antisolvent is dosed inside the crystallizing solution by means of the membrane. Static (quiescent) and dynamic process can be performed. In the first case, the feed and the distillate solutions are quiescent, while in the second case, those two solutions are circulated

in forced solution flow environment, generally in a condition of laminar flow.

Generally, in order to avoid wetting, hydrophobic membrane materials are preferred for aqueous feed solutions, while hydrophilic membranes can be used for oleophilic solutions. In the most common arrangement, the distillate side of the membrane consists in a condensing fluid, often the pure solvent, at a lower temperature than the feed side in the case of thermal activation of the driving force, or in a stripping solution consisting in a hypertonic solution of inert salts (NaCl, MgCl₂, CaCl₂, etc.) in the case of the isothermal configuration.

While for the crystallization of inorganic substances or low molecular weight organic compounds, the thermal system can be affectively used, for the crystallization of heat-sensitive molecules, like proteins, the osmotic configuration appears more appropriate tank to its milder operating conditions (Curcio et al. 2001).

Solvent Swollen Polymer

Annarosa Gugliuzza
 Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Swollen polymers are classically named as gels, although the nature of the dissolved solvent allows distinguishing between three main classes of compounds: aerogel or xerogel when the network spaces are full of air, hydrogel, and organic gel when embedding water or oil. The swelling is defined as a penetration of a solvent into the polymer network that causes an abrupt change in the

volume (Gugliuzza and Drioli 2007), moving the boundary from unsolvated glassy region to solvated and expanding rubbery domain. This event occurs when there are unbalanced osmotic forces and viscoelastic restoring forces, while it is stopped when these forces reach the equilibrium. The opposite event is when the solvent releases from the polymer matrix, thereby causing deswelling.

Both the neutral and ionic polymers can swell, and different forces can take place during expansion, such as hydrophilic/hydrophobic and/or ionic interactions. The degree of crystallinity, cross-linking, as well as the strength of attractive and repulsive forces can seriously affect the intensity of the swelling (Flory and Rehner 1943).

Thermodynamically, the behavior of a swollen polymer can be described by the total free energy (ΔG_{total}), expressed as the sum of the free energy of mixing (ΔG_{mix}) and the elastic free energy (ΔG_{el}). An additional energetic term, such as the ionization free energy (ΔG_{ion}), must be also included when the polymer is a polyelectrolyte. Kinetically, the swelling event can be studied on the basis of the solvent diffusion rate and can be classified as Fickian or non-Fickian depending on the polymer chain relaxation (Crank and Park 1951). In a Fickian diffusion, the solvent rate is usually slower than relaxation rate of the segment chains (Case I transport), while in a non-Fickian diffusion, the solvent moves quicker than chain relaxation (Case II transport) or with a comparable rate (anomalous transport) (Berens and Hopfenberg 1978).

A somewhat simplified and empirical equation to study the diffusion through the polymers is

$$\frac{M_t}{M_\infty} = kt^n \quad (1)$$

where M_t and M_∞ are the mass uptake at time t and equilibrium, t and n are constants related to polymer-solvent systems. The type of diffusion can be established from the diffusional constant n . Value equal to 0.5 indicates Fickian diffusion; $0.5 < n < 1.0$ values are typical of anomalous transport, while values equal to 1 are estimated for Case II transport.

Better models have been proposed to study the non-Fickian diffusion. The following relation has been, for example, proposed for systems wherein M_t/M_∞ ratio is 0.60 (Crank and Park 1951):

$$\frac{M_t}{M_\infty} = (1 - Ae^{-k_2 t}) \quad (2)$$

A is a constant and is calculated together with k_2 from the slopes and intercepts of the plot of $\ln(1 - M_t/M_\infty)$ versus time t at times later than those corresponding to $M_t/M_\infty = 0.60$.

Instead, relation 3 well describes the anomalous transport:

$$\frac{M_t}{M_\infty} = k_1 t + k_2 t^{\frac{1}{2}} \quad (3)$$

where $K_1 t$ expresses the relaxation-controlled process, while $k_2 t^{1/2}$ quantifies the dependence of the transport on diffusion.

A discontinuity of the volume transition can be observed in many gels, thereby leading the polymer from a swelled to a shrunk state and vice versa, depending on the predominance of unbalanced hydrophobic/hydrophilic and/or ionic forces. Formation or destruction of hydrogen bonding as well as the interactions with counterions in specific chemical environments can decide the expansion or the collapse of the polymer network, making smart gels/membranes whereby a transport phenomenon can reversibly be controlled (Chaterji et al. 2007; Diaconu et al. 2012).

Organic solvent nanofiltration (OSN)

Solvent-resistant nanofiltration (SRNF) is a pressure-driven technique to realize separations up to the molecular level in solvent streams (Vandezande et al. 2008). Small solvent molecules will permeate through the membrane, while solutes (with a molecular weight between 200 and 1000 Da) will be retained. Applications are widespread and mainly found in the (petro) chemical, pharmaceutical, and food industry. A good SRNF membrane is characterized by an excellent performance (high flux as well as high selectivity); long-term mechanical, chemical, and thermal stability; low fouling tendency; and a cost-effective and defect-free production.

Both ceramic and polymeric membranes can be applied in SRNF. Ceramic membranes are often synthesized from alumina, zirconia, or titania. Considering chemical, thermal, and physical stability, these membranes are most robust. They are able to combine a good selectivity with a long lifetime. However, ceramic membranes are expensive due to a complicated large-scale production process, rather brittle and intrinsically hydrophilic (low flux in apolar solvents unless surface treated). Therefore, polymeric membranes are considered to be the most interesting material

Solvent-Resistant Nanofiltration, Table 1 Suppliers of commercial SRNF membranes and their products (as in October 2012)

Company	Membrane	Material	Stability range	MWCO
Evonik (Germany) ^a	DuraMem [®]	Lenzing P84 [®] polyimide (*cross-linked)	Acetone, ethanol, methanol, tetrahydrofuran, dimethylformamide*, dimethyl sulfoxide*, dimethylacetamide*, isopropanol, acetonitrile, methyl ethyl ketone, ethyl acetate, and more	150–900 Da

for SRNF applications. Advantages are the large variety of available polymers, their relatively low price, and the ease of processing and upscaling. An important issue with polymeric membranes is their limited thermal and chemical stability. Interactions between organic solvent and membrane can cause these membranes to swell extensively (or even dissolve) resulting in loss of selectivity. Cross-linking of the membrane matrix is often performed to increase the polymer stability in strong solvents (e.g., dimethylformamide). Cross-linking can be achieved chemically, thermally, or by irradiation (UV, plasma). Typical cross-linked polymers for SRNF are polyimide, polydimethylsiloxane, and polyacrylonitrile.

Polymeric membranes mostly have an asymmetric structure consisting of a thin, dense top layer on a porous support. They can be divided into two categories: integrally skinned and composite materials (Peeva et al. 2010). The first are synthesized via phase inversion, in which a polymer film is transformed from a liquid to a solid state in a controlled manner. The latter consist of two different materials, where the porous support

is often prepared via phase inversion, while the dense layer is put on top via a different technique (e.g., dip or spin coating, interfacial polymerization, grafting).

Transport through SRNF membranes is complex due to the interactions between solvent, solute, and membrane (e.g., swelling). Two models are often applied to describe the transport mechanism but also the combination of both appears. For loose SRNF membranes, the pore-flow model is used while the solution-diffusion model is applied for dense SRNF membranes. Both take into account membrane properties, which can vary depending on the feed characteristics. This implies that the same membrane can behave as loose in one solvent and as dense in another solvent.

Currently, only a limited number of companies supply commercial SRNF membranes (listed in Table 1). In the past, Koch Membrane Systems (USA) was another producer of SRNF membranes (MPF series), but they ceased their SRNF production. Together with StarMem (MET-Evonik, previously Membrane Extraction Technology), the MPF membranes were the first

commercially available SRNF membranes, making them the subject of many studies. Evonik, SolSep, and Borsig offer polymeric membranes in flat sheet form or spiral-wound modules. Inopor supplies ceramic mono- and multichannel tubes.

SO_x, Effect on Membrane Properties

Colin A. Scholes

Department of Chemical and Biomolecular Engineering, University of Melbourne, Parkville, VIC, Australia

The combustion of sulfur-containing fuels, such as coal, results in the production of SO₂ and SO₃, commonly collectively referred to as SO_x. The typical coal-fired power station flue gas has SO_x concentrations between 1000 and 5000 ppm in their untreated flue gas, dependent on the sulfur content of the coal, of which the main component is SO₂. The contribution of SO_x to acid rain has meant that their emissions have been heavily regulated for over 30 years. The similar chemical properties between SO_x (in particular SO₂) and CO₂ also correlate into the behavior of SO_x in membrane separation processes.

The high molecular weight of SO₂ and SO₃ relative to other components of flue gas means that for Knudsen diffusion-based membranes, the SO_x components will remain in the retentate.

SO_x, Effect on Membrane Properties, Table 1 SO₂ permeabilities (barrer) and SO₂/CO₂ selectivity in a range of polymeric membranes

	SO ₂ permeability	SO ₂ /CO ₂
Cellulose triacetate	270	48
Polyacrylate	1,700	41
Polyethylene glycol	4,100	44
Polyamide-6-b-ethylene oxide	1,000	7.6
Polytetrafluoroethylene-co-ethylene	2.6	1.32

Similarly, the large kinetic diameters of SO₂ and SO₃, both greater than CO₂, means for molecular sieve based membranes the SO_x components of flue gas will leave the membrane module mainly in the retentate stream (Scholes et al. 2009). However, SO₃ and to a less extent SO₂ are strongly condensable gases, much greater than CO₂. Hence, for surface diffusion and capillary condensation separation, it may be possible for porous membranes to be selective for SO_x.

Solution diffusion-based nonporous membranes have been studied for SO_x separation, because of membrane research in the 1970s on desulfurization of flue gas. A list of polymeric membrane SO₂ permeabilities are provided in Table 1, along with SO₂/CO₂ selectivity. The majority of polymeric membranes show SO₂ selectivity, because of the stronger condensability of SO₂ (Felder et al. 1975). The relationship between SO₂ permeability and SO₂/CO₂ selectivity follows a typical Robeson upper bound plot. To date no permeability data has been reported for SO₃ through a nonporous membrane. This is probably because pure SO₃ is a liquid at room temperature and experimentally difficult to handle. However, given the strong condensable state of SO₃ compared to SO₂ and CO₂, it is reasonable that SO₃ will experience a greater permeation through glassy polymeric membranes than either SO₂ or CO₂.

SO₂ is a known plasticizer of polymeric membranes, producing a more rubbery material and increasing the diffusivity of penetrants. Its plasticizing effect is believed to be stronger than CO₂, though this has only been confirmed for

polyvinylidene (Zavaleta and McCandless 1976). In many industrial processes where SO_x is present, there exist high levels of water vapor. This allows for the generation of sulfuric acid, which results in membrane degradation. For example, cellophane-based membranes experience a 30-fold increase in SO₂ permeability when water is present, associated with increased free volume within the membrane because of acidic degradation (Hanousek and Herynk 1962). The fact SO₃ is a liquid at ambient temperature means it is very likely to have the same plasticization and degradation effect on polymeric membranes as SO₂.

$$\begin{aligned} \min_x \quad & f(x) \\ \text{s.t.} \quad & h(x) = 0 \\ & g(x) \leq 0 \end{aligned}$$

Spacer Arm Length

Jiahui Shao
School of Environmental Science and Engineering, Shanghai Jiao Tong University, Shanghai, China

The spacer arm length refers to the length of hydrocarbon chain between the solid support and the functional ligand.

For ion exchange and affinity chromatography/membrane, studies have demonstrated that the spacer arm length can affect the overall system performance. In general, when the immobilized

ligand is a small molecule, such as a receptor substrate or a chemical antigen, steric hindrance occurs between the immobilization support and the substance to be isolated. This phenomenon may cause a reduction or complete lack of specific binding (Zou et al. 2001). To overcome this problem, it is often necessary either to select a different support (i.e., one with a spacer arm already attached) or to bind a spacer molecule to the support prior to attaching the ligand. An optimal spacer arm ensures that the functional groups are placed a suitable distance from the surface of the solid support and are easily accessible to the macromolecules. An ideal spacer arm should have (1) proper length (at least three atoms), (2) no active center that could cause nonspecific adsorption, and (3) at least two functional groups, one to react with the base support and one to serve as the chromatographic ligand (Zou et al. 2001).

For charge-modified membranes with different spacer arm lengths, recent researchers demonstrated that the spacer arm length can have a strong effect on the performance characteristics of electrically charged membranes by electrostatic exclusion effects. Even though the hydraulic permeabilities of these membranes were essentially identical, membranes with larger spacer arm length have greater retention of a like-charged molecule. The greater retention with larger spacer arm length is directly related to the effective surface charge or apparent zeta potential (Rohani and Zydney 2010; Shao et al. 2013). The permeability-selectivity trade-off plot for the charge-modified membranes with different spacer arm length demonstrated that the electro-static interactions led to much better ultrafiltration performance of enhanced selectivity and permeability than could be obtained with conventional (neutral) membranes. Figure 1 shows a plot of the selectivity (or separation factor) as a function of the permeability for cytochrome c for unmodified and positively charged versions of composite regenerated cellulose ultrafiltration membranes. The format for plotting the data is analogous to the classical Robeson plot used to analyze the behavior of gas separation membranes. High-performance membranes would lie in the upper right hand corner of the plot, having both large selectivity and large

Spacer Arm Length,

Fig. 1 Permeability-selectivity trade-off for cytochrome c using unmodified and positively charged Ultracel™ membranes. The solid and dashed curves represent model calculations for an uncharged membrane and a positively charged membrane consisting of a parallel array of cylindrical pores with a log-normal pore size distribution (Rohani and Zydney 2010)

permeability. Unmodified and po. For example, at a hydraulic permeability of about 6.0×10^{-10} m/s/Pa (15 L/m²/h/psi), the selectivity for the positively charged membrane is more than three orders of magnitude larger than that of the unmodified membrane. The charge-modified membranes with different spacer arm lengths can be well exploited to enhance the performance of ultrafiltration processes for real applications. Mehta and Zydney (2008) generated a series of positively-charged membranes with different spacer arm length by activation of base cellulose membrane with epichlorohydrin followed by reaction with diamines having different numbers of alkyl groups between the two amines. Experimental data showed that at low ionic strength (5 mM), the observed sieving coefficient for cytochrome c through the 30 kDa membrane made with 1,10-diaminodecane ($n = 10$) was more than an order of magnitude smaller than that for a similar membrane made using 1,2-diaminoethane ($n = 2$) even though these membranes had very similar hydraulic permeabilities and pore size distributions, where n is the number of alkyl groups between the amine functionalities. This large reduction in the protein sieving coefficient was found to be consistent with the observed increase in the membrane zeta potential, which was most likely due to the increase in net charge associated with the reduction in electrical

interactions between the two amine groups in the diaminodecane in combination with the greater displacement of the charge functionality into the interior of the membrane pore for the larger ligand. Later, Shao et al. (2013) generate a series of negatively charged ultrafiltration membranes that differed in spacer arm length by covalent attachment of negatively charged group to a commercially available regenerated cellulose membrane. Results indicated that the membrane with larger spacer arm length has better rejection of humic acid and less membrane fouling compared to that with smaller spacer arm length, which is also consistent with the larger charge of the membrane having larger spacer arm length.

Spacer-Filled Channels

Stanislaus Raditya Suwarno
Singapore Membrane Technology Centre,
Nanyang Technological University, Singapore,
Singapore

Spacer-filled channels refer to the use of feed channel spacer in flat sheet and spiral-wound membrane processes. Feed channel spacer is an essential part in spiral-wound module to separate membrane leaves (Fig. 1). There are many different types of feed spacers in the market, but the most commonly used feed spacers are ladder and diamond type (Fig. 2). They differ in the orientation of the spacer in touch with the flow direction. Feed spacers are usually made of plastic polypropylene (PP). The opposite of spacer-filled channel is called empty channel in which simply no spacer is placed on top of the membrane.

One of the most important geometric characteristic of spacers is spacer voidage (ε), which is a product of the mesh size (l_m), diameter of

filaments (d_f), spacer height (h_{sp}), and angle between filaments (θ) (Da Costa et al. 1994):

$$\varepsilon = 1 - \frac{\pi d_f^2}{2 l_m h_{sp} \sin \theta}$$

The presence of spacer reduces the average cross-sectional area of the channel, which results in the correction of effective crossflow velocity (u_x) from original superficial crossflow velocity (u_v):

$$u_x = \frac{u_v}{\varepsilon}$$

where u_v is given by the total flow rate divided by the total cross-sectional area.

In reverse osmosis or nanofiltration processes, spacer filled channels provide better membrane performance than empty channels by lowering trans-membrane pressure (TMP) which is caused by the reduction concentration polarization (CP). CP is the exponential ratio of flux (J_v) and mass transfer coefficient (k_m):

$$CP = \exp\left(\frac{J_v}{k_m}\right)$$

Spacer-Filled Channels, Fig. 1 Spiral-wound module

Spacer-Filled Channels,
Fig. 2 Most common feed
channel spacers (a) Ladder.
(b) Diamond

k_m is greater in spacer filled channels than in empty channels. At constant flux membrane operation, the relationship between J_v , CP, and TMP is shown below:

$$J_v = \frac{TMP - CP \Delta \pi_w}{\mu R_m}$$

Where $\Delta \pi_w$ is the osmotic pressure difference between feed and permeate sides, μ is the solution viscosity, and R_m is membrane resistance.

In membrane operations which rely on temperature difference (e.g., direct contact membrane distillation), temperature polarization – temperature difference between bulk and on the membrane surface – causes significant loss to the thermal driving force (Phattaranawik et al. 2003). Feed spacers help to reduce temperature polarization by increasing heat transfer and further results in higher permeation flux.

The disadvantage of spacer feed channels is the elevated channel pressure drop (ΔP). ΔP is very sensitive to crossflow velocity (u_x) where spacer causes flow blockage and increases u_x :

$$\Delta P_{CH} = \frac{\rho u_x^2}{2} \cdot \frac{A'}{\text{Re}^n} \cdot L_{CH}$$

where ρ is solution density, L_{CH} is channel length, Re is Reynolds number, and A' is constant.

Increased mass transfer coefficient in spacer-filled channels provides reduction to the rate of membrane fouling. Effectiveness of spacer toward fouling reduction has been tested on colloids, protein (Schwinge et al. 2000), and biofouling (Suwarno et al. 2012). In biofouling however, presence of spacers may also be problematic as biofilm may grow on the spacers and increase channel pressure drop (Vrouwenvelder et al. 2009). One must note that spacers do not completely stop fouling. In fact, in some situation spacers may provide several dead zones which may cause deposition of high level of foulants. Selection of suitable type of spacer configurations (voidage, size, etc.) to reach optimal operations is dependent on operating conditions (crossflow velocity, feed type, etc.).

Spin Coating

W. J. Lau

Advanced Membrane Technology Research Centre (AMTEC), Universiti Teknologi Malaysia, Skudai, Johor, Malaysia

The technique of spin coating is widely used in many industrial processes, in particular microelectronics industry to apply a uniform photoresists and photolithographic film onto silicon wafers. This coating technique is also used in the preparation of composite membrane but only at the laboratory scale. It is reported that the membranes prepared by spin-coating technique could have thicknesses in the range of 0.5–30 μm (Baker 2012; Wang et al. 2011) which is significantly thinner than those of membranes made of casting technique using knifelike tool, i.e., between 80 and 250 μm . Since membrane is a pressure-driven process, the thinner the membrane layer, the lower the transport resistance of water which as a consequence can lead to greater water permeability. However, it must be pointed out that spin coating is limited to flat substrates, which limits its

Spin Coating,**Fig. 1** Schematic of a spin-coating process (Norrman et al. 2005)**Spin Coating,****Fig. 2** Factors affecting the membrane properties during spin-coating process

applicability on the circular-shaped objects such as hollow fiber and tubular membranes.

Figure 1 illustrates a schematic of a lab-scale spin coater (also known as spinner). Prior to spin coating, an excess of polymeric solution is applied to the center of the circle plate made of either glass or stainless steel material. It is followed by rapid acceleration of the plate to the desired rotation rate (angular velocity) at a given duration of spinning. In the spin-coating process, polymeric solution flows radially due to the action of centrifugal force, causing the excess solution ejected off the edge of the plate. As the solvent used to dissolve polymer is volatile, an ultrathin layer of film is thus produced on the plate surface due to a dramatic rise in film viscosity caused by solvent evaporation. After coating process, the nascent membrane together with the plate is immersed into water coagulation bath in which phase

inversion takes place and a membrane is produced. The resulting membrane is further immersed in another water bath for another day in order to completely remove the residual solvent from membrane prior to use.

There are many factors governing the thickness and morphology of the membrane produced via spin coating. As shown in Fig. 2, the properties of the membrane prepared from spin coating can be affected by both polymeric solution and the spinning conditions. For instance, the thickness of film increases with decreasing spin speed or decreases with decrease in viscosity of solution (Norrman et al. 2005; Hall et al. 1998). The solution viscosity is in general dependent on the polymer concentration and type of polymer used in the preparation of solution in which the higher the polymer concentration and the higher the molecular weight of polymer used in the solution

Spin Coating, Fig. 3 Cross section and top-surface morphologies of the membranes prepared from different spinning times with spin speed of 3,000 rpm, (a) 60 s, (b) 120 s, (c) 180 s, and (d) 240 s (Wang et al. 2011)

preparation, the greater the viscosity of solution produced. Increase in spinning time on the other hand has potential to produce thinner membrane with more visible pores on the surface. It is reported in the work of Wang et al. (2011) that the polyvinylidene fluoride (PVDF) membrane layer tended to become thinner, while its surface pore became more visible with increasing spinning time from 60 to 240 s as shown in Fig. 3. It must be also noted that at prolonged spinning time (240 s), the cross-sectional structure of the membrane became more porous and disordered which could be the result of the evaporation-induced phase separation instead of nonsolvent (water)-induced phase separation.

Spin Coating Interfacial Polymerization (IP) Techniques

W. J. Lau

Advanced Membrane Technology Research Centre (AMTEC), Universiti Teknologi Malaysia, Skudai, Johor, Malaysia

The use of spin coating interfacial polymerization (IP) technique in the preparation of thin-film composite membrane is rarely been reported in the literature, although it involves very similar procedure as the conventional IP technique. As illustrated in Fig. 1, it can be seen that instead of pouring organic solution directly on the surface of substrate containing amine monomer, the organic solution is spin coated over the substrate surface using the spin coating IP technique which is also known as dynamic IP. Owing to rapid acceleration of the spinning plate to the desired rotation rate, a powerful centrifugal shearing force is created which spreads away the organic solution from the axis of rotation toward the substrate outer edge. Because of this, it results in the IP reaction between the acyl chloride monomer in the organic solution and the amine monomer on

Spin Coating Interfacial Polymerization (IP) Techniques, Fig. 1 Preparation of thin-film composite polyamide membranes through different interfacial polymerization (IP) techniques, (a) static IP (conventional IP) and (b) dynamic IP (spin coating IP) (Reprinted (adapted) with permission from (An Q, Hung

WS, Lo SC, Li YH, Guzman MD, Hu CC, Lee KR, Jen YC, Lai JY (2012) Comparison between free volume characteristics of composite membranes fabricated through static and dynamic interfacial polymerization processes, *Macromolecules* 45: 3428–3435). Copyright (2012) American Chemical Society)

the substrate surface, creating a very thin polyamide (PA) layer on the top of the substrate with good uniformity. It is also reported that by using this dynamic IP technique, molecular chains are oriented in the horizontal direction and stacked up closer to one another in comparison to the vertical growth direction found in the conventional IP technique (An et al. 2012). Conventional IP is static which allows amine and acyl chloride monomers to contact each other and stand for some time before a polymer film is formed at the interface between aqueous and organic solution.

Similar to the typical spin coating process (Norrman et al. 2005; Wang et al. 2011), there are several variables that have influential role in affecting the properties of PA layer formed during spin coating IP process. These include spinning speed, spinning duration, temperature, and humidity. In addition to this, the organic solution properties which depend on the factors such as type of monomer and its concentration as well as solvent volatility might also have the potential to affect the cross-linking degree of PA structure (Lau et al. 2012).

Figure 2 compares the top and cross-sectional structures of the thin-film composite PA membranes prepared from two different IP techniques. With respect to the thickness of PA layer, it is found that the composite membrane prepared from spin coating IP technique has a significantly thinner selective layer than that of a membrane made of conventional IP technique. Furthermore, the spin-coated PA layer possesses smaller cavities as evidenced on the cross-sectional image of TEM. This phenomenon is mainly due to the minimum amount of water left within the PA film because water is significantly drawn out during spinning process due to the powerful centrifugal force. The water (in the PA matrix) then evaporates during drying and leaves behind small cavity as explained by An et al. (2012). In addition, several parallel lines are clearly observed on the spin-coated PA layer which is most likely due to the rotation effect of spinning, creating wavy fluid flow pattern on membrane surface. The presence of parallel lines is believed to cause the membrane surface roughness to increase, resulting in different membrane separation performances. It must be pointed out that the integration

Synonyms

[Spiral wound membrane](#); [Spiral wound module](#)

A number of membrane module designs are possible, and all are based on two types of membrane geometry: (i) flat sheet membranes and (ii) capillary fibers. Plate-and-frame as well as spiral wound modules house flat membranes (Mulder 1997).

The spiral wound module is an important module type for membrane applications. Initially it was developed for reverse osmosis applications and is nowadays also used in ultrafiltration and gas permeation applications (Blackmer and Hedman 1979).

Spiral wound modules are used where pressure drop has to be considered and when counter current flow is not needed to maximize separation efficiency. Higher pressure applications involving costly pressure vessels and piping make the hollow fiber

Spiral Wound Membrane

► [Spiral Wound Membrane Module](#)

Spiral Wound Membrane Module, Fig. 1 Schematic drawing of a spiral wound module taken from Scholz et al. (2011)

modules more favorable because this reduces the component costs of the system by as much as a factor of ten in some cases (Koros and Fleming 1993).

The spiral wound module is the next logical step from a flat membrane. It is in fact a plate-and-frame system wrapped around a central collection pipe, similar to a sandwich roll. Feed and permeate-side spacer material is glued along three edges to build a membrane envelope. A feed-side spacer is separating the top layer of two flat membranes simultaneously acting as a turbulence promoter (Fig. 1; Mulder 1997).

The feed flows in axial direction over the envelopes built up by two membrane stacks. The permeate is collected on the inside of the envelope and spirals into the central permeate collection pipe. The packing density of this module ($300\text{--}1,000\text{ m}^2/\text{m}^3$) is greater than that of the plate-and-frame module but strongly depends on the channel height, which in turn is determined by the thickness of the permeate and feed-side spacer material (Mulder 1997). The spacer is not only used to keep the distance between the membranes, but it also enhances the mass transfer at a minimum pressure drop (Blackmer and Hedman 1979). Net-type spacers are common for spiral wound modules. Important characteristics determining the module performance influenced by this type of spacer are:

- Filament diameter
- Hydrodynamic angle
- Mesh size

- Voidage
- Position to flow (transverse)

The analysis of pressure drop within spacer-filled channels can be found in Baker et al. (2010). Recently a double helix spacer with enhanced mass transfer characteristics combined with a reduced pressure drop was developed at RWTH Aachen University (Feng and Ivory 2000).

Several (up to 6) spiral wound modules are assembled in one pressure vessel and are connected in series via the central permeate tubes (Fig. 2; Mulder 1997; Blackmer and Hedman 1979). New vessel designs currently emerge that addresses the huge gas flows to be potentially treated in post combustion CO_2 capture (Bao and Lipscomb 2002).

The advantages of spiral wound modules are the following (Caro et al. 2007):

- Simple, cost-effective construction
- Relatively high packing density/membrane area to volume ratio (up to $1,000\text{ m}^2/\text{m}^3$)
- Good mass transfer due to feed spacer

The disadvantages are the following:

- Long permeate path
- Difficult to clean

In total up to 20 % of the commercial gas separation membranes are being formed into spiral wound modules (Baker 2002).

Spongelike Structure

Tao He

Lab for Membrane Materials and Separation Technology, Shanghai Advanced Research Institute CAS, Shanghai, China

Spongelike structure is a common membrane sub-layer morphology as shown in Fig. 1. Two types of spongelike structure may be identified: an interconnected network type (Fig. 1a) and a closed-cell type (Fig. 1b) characterized as individual separate cells. An ideal asymmetric membrane consists of a thin skin layer and an interconnected porous substructure. High interconnectivity, an important but difficult to be quantified property, of the porous substructure is crucial for low mass transport resistance. It is favorable due to the better mechanical properties than the fingerlike structure.

Formation of spongelike structure has the same origin as the fingerlike structure, liquid-liquid phase separation. Thermodynamically the liquid-liquid demixing of a polymer solution follows possibly two mechanisms: binodal demixing or spinodal demixing (Marcel 1996). In binodal demixing, once the nucleation of the polymer-lean phases is initiated, the growth of the nuclei proceeds until the net inflow of solvent or nonsolvent adjacent to the polymer-lean phases ends and/or the polymer-rich phases follow a glass transition (Li et al. 1996). In case of a crystalline polymer, a solid-liquid phase separation takes place; consequently, crystallization of the

Spiral Wound Module

► Spiral Wound Membrane Module

Spongelike Structure, Fig. 1 Spongelike structure of PES membranes. **a** Open-pore interconnected structure; **b** closed-cell structure

polymer-rich phases blocks the growth of the polymer-lean phases.

If the phase separation follows a spinodal demixing, myriads of polymer-lean phases are initiated at a short-time scale; the probability for the polymer-lean phases to get in touch with each other is high, leading to an open porous structure. For a semicrystalline polymer, closed pores may be opened up by an extra stretching step, followed by the solid-liquid demixing; thus a spontaneous demixing is not necessary. Some tips to prepare spongelike particularly interconnected porous structure include: (1) addition of pore-former additives (both small molecular weight and polymeric) (Boom et al. 1994), (2) selection of solvent/coagulant pair with strong interaction (to promote instantaneous demixing, thus favorable for spinodal demixing), and (3) decrease in the polymer concentration.

Spray Coating

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

Coating

A coating is applied to the surface of an object to protect it from environmental effects or to enhance its surface properties such as appearance, corrosion resistance, wear resistance, scratch resistance, adhesion, wettability, dielectric property, electrical conductivity, etc. The object to be coated may also be referred as substrate. In some cases, the coatings act as an essential part of the finished product such as in the case of semiconductor devices fabrication where the substrate material is silicon wafer.

Coatings may be applied as liquids, gases, or solids. “The coating which is applied on an object with a liquid spray is known as spray coating.”

Suspension and solution thermal spraying are the emerging methods of coating (Pawlowski 2009). Thermal spraying is a process that utilizes thermal energy to melt material in powder, wire, or rod form followed by providing kinetic energy to the molten or semi-molten material to propel it toward a prepared surface by expanding process gases. The impact of these molten or semi-molten particles on

the surface of substrate creates a coating buildup called spray coating. Thermal spraying could be achieved by various techniques including:

Plasma Coating

In plasma spray method, plasma gas such as argon/hydrogen or argon/hydrogen is heated by an arc between the two electrodes. This heating process causes expansion of plasma gas which accelerated through a shaped nozzle, creating very high velocity. Temperature of the plasma gas in the arc zone approaches about 20,000 K which remains up to 10,000 K even after exiting from the nozzle for several centimeters. This stream carries the coating material in molten form and applies to the substrate. Plasma spray coatings are commonly used in jet engines where it provides high-temperature protection to the parts which are exposed to combustion gases. This increases the life and efficiency of the system.

Electric-Arc Spray

An electric arc is created when two conductive wires carrying charges of opposite polarity meet in front of spray device. This electric arc melts the wires which are acting as feedstock for coating. Electric-arc spraying technique has the fastest coating rates among coating technologies. Flame or plasma is not involved in this coating technique which significantly reduces the heat transfer to the substrate material, making the process thermally efficient. The electric-arc spray is commonly used in the automotive industry and to coat large objects such as bridges with aluminum and zinc which provide corrosion resistance properties.

High-Velocity, Oxy-Fuel (HVOF) Coating

HVOF utilizes an extended nozzle to heat and accelerate the coating material. Typical HVOF devices operate at hypersonic gas velocities which provide kinetic energy helping to produce

dense and well-adhered coatings. HVOF coatings can be used for coating the high-tech medical devices and coating of carbide material to bolts used in agricultural machine which greatly extends the life of the bolt.

Flame Spray

Flame spray uses combustion of gases to melt powder, wire, or rod material and propels the molten droplets onto a surface to create a coating. Flame coatings are commonly used for materials requiring good wear resistance and excellent impact resistance such as agricultural harvesting components, oil-drilling parts, etc.

Cold Spray

Cold spray is technically not a thermal spray process since it does not use thermal energy as the primary energy source. In cold spraying, particles are accelerated to very high speeds by the carrier gas forced through a converging–diverging de Laval type nozzle. High-energy impact of feedstock solid particle causes plastically deformation of particles at substrate surface which subsequently bond metallurgically to the substrate to form a coating. The velocity is an important parameter to obtain such coating, and critical velocity value for bonding depends on the material properties such as nature of feedstock, powder size, and temperature. Some hard materials are also reported, but soft metals such as Cu and Al are best suited for cold spraying process (Seiji et al. 2008).

SPS/PES Asymmetric Blend Nanofiltration Membrane

Yuzhong Zhang

School of Material Science and Engineering,
Tianjin Polytechnic University, Tianjin, China

An SPS/PES asymmetric blend nanofiltration (NF) membrane is a novel semipermeable membrane used in nanofiltration process, such as water treatment for drinking water production, desalination, concentration, and purification and pharmaceutical and chemical industries. SPS/PES asymmetric blend nanofiltration membranes are developed in 2011 by Senuo Filtration Technology (Tianjin) Co., Ltd (Chen et al. 2011).

A nanofiltration membrane is a type of pressure-driven membrane with properties in between reverse osmosis (RO) and ultrafiltration (UF) membranes, with a membrane pore size between 0.5 and 2 nm, nominal molecular weight cutoffs from 200 to 1000 Da, and operating pressures between 5 and 40 bar (Hilal et al. 2004).

Most nanofiltration membranes are composite membranes produced via sophisticated fabrication processes, such as coating or interfacial polymerization, where the top selective layer and bottom porous substrate of the membrane can be independently modified and optimized (Lau et al. 2012; Mulder 2009). The fabrication processes for composite membrane in general involve various preparation conditions, making the entire process very labor intensive.

Asymmetric blend nanofiltration membranes are made by non-solvent-induced phase separation, which is a single-step process. Non-solvent-induced phase separation technology is a relatively simple preparation technique compared to composite membrane fabrication technology. And

also, the blending technique has the advantage of combining the positive features of each component while being very simple.

SPS/PES asymmetric blend nanofiltration membranes are fabricated by blending polyethersulfone (PES) with sulfonated polysulfone (SPS) as membrane material. PES is one of the important polymer materials in membrane fabrication, due to its excellent mechanical strength and thermal and chemical stability. PES also allows easy manufacturing of membranes, with reproducible properties and controllable size of pores down to several decade nanometers. Polyethersulfone repeating unit is shown in Fig. 1.

PES is also an inherently hydrophobic polymer. A wide range of evidence shows that membrane with adequate hydrophilicity can prevent deposition of many solutes such as protein, which can increase resistance to fouling. However, hydrophobicity of PES has limited its application in NF membrane preparations. Introducing sulfonic groups to membrane is an efficient way to improve the hydrophilicity of PES membrane, which can be carried out through the introduction of sulfonic groups directly into PES or by blending with another sulfonated material, such as sulfonated polysulfones (SPSs). Sulfonated polysulfone (repeating unit shown in Fig. 2) with hydrophilic group, sulfonic group, has adequate hydrophilicity. The high hydrophilicity can improve the water flux and pollution resistibility. But sulfonated polysulfones possess weak strength, which will cause bad stability for operation. The miscibility of PES with SPS is better enough. Sulfonated polysulfone can be induced to increase hydrophilicity of the PES nanofiltration membrane.

Besides increasing hydrophilicity, sulfonated polysulfone offers another advantage, negative

SPS/PES Asymmetric Blend Nanofiltration Membrane, Fig. 2 Sulfonated polysulfone repeating unit

SPS/PES Asymmetric Blend Nanofiltration Membrane, Fig. 3 Typical cross section morphology of SPS/PES asymmetric blend nanofiltration membrane

charge. Membranes with fixed charges are predicted to exclude solutes or colloids bearing the same sign of charge and to decrease membrane fouling. SPS/PES asymmetric blend nanofiltration membranes with functional group, sulfonic group, can gain negative charges and give them great selectivity with respect to ions or charged molecules.

SPS/PES asymmetric blend nanofiltration membranes are primarily characterized by pure water flux, rejection, and hydrophilicity.

An SPS/PES asymmetric blend nanofiltration membrane is a combination of good hydrophilicity and mechanical strength, which can improve the water flux, antipollution ability, and stability of blend membrane. The negative charge due to sulfonic group leads to a high selectivity over ions or molecules with positive charges.

The SPS/PES asymmetric blend nanofiltration membrane has the asymmetric morphology, as shown in Fig. 3. Blending of PES with SPS in the casting dope leads to interesting asymmetric structure. There are fingerlike macropores and spongelike pores in SPS/PES membranes. A dense layer supported on a porous layer, as shown in Fig. 4.

Stack of Single Cells in Electrodialysis

Tanja Vidakovic-Koch

Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany

Electrodialysis is an electrochemical process (see “► [Electrochemical Processing](#)”) for separating an aqueous feed solution into a concentrate or brine and dilute or desalted water by means of an electrical field and ion-selective membranes. Electrodialysis takes place in an electrodialysis stack. A schematic representation of such a stack with anion- (A) and cation- (C) exchange membranes arranged in an alternating series pattern is shown in Fig. 1. For practical application, number of membranes in an electrodialysis stack is much higher than shown in Fig. 1. For example, such stacks might contain up to 600 pairs of membranes (a unit cell is a combination of one cation-exchange membrane and one

anion-exchange membrane) (Seader and Henley 2006). The size of a membrane is usually between 0.4 and 1.5 m² and they are separated from each other by spacer gaskets. A typical voltage drop across the unit cell is 0.5–1.5 V and typical current densities are in the range of 5–50 mA cm⁻². The movement of ions in the electrodialysis stack is dictated by the direction of an electrical field and allowance of a membrane for an ion transport. For example, in compartments 3, 5, and 7 (Fig. 1) under influence of the electrical field cations will move across cation-exchange membrane and anions across anion-exchange membrane, resulting in formation of dilute. On the other hand, in compartments 2, 4, 6, and 8 the anion- and cation-exchange membranes do not allow movement of ions in the direction of electrical field, resulting in formation of concentrate in this compartments. As in other electrochemical processes, ionic current will be finally transformed into electrical current by means of electrochemical reactions taking place at the cathode and anode. The main application of electrodialysis is the desalination of brackish water. Other applications include waste water treatment, separation of salts, and some food industry applications.

Typical ion-exchange membranes are made of polystyrene, containing fixed sulfonate $-\text{SO}_3^-$ groups (cation-exchange membrane) or quaternary

Stack of Single Cells in Electrodialysis, Fig. 1 Schematic representation of the electrodialysis process. C cation-exchange membrane, A anion-exchange membrane

ammonium groups such as $-\text{NH}_3^+$ (anionexchange membranes) (2008). The thickness of the membranes is 0.2–0.5 mm and they are reinforced to provide better mechanical stability. The membranes are wetted with water, but due to the size of pore networks inside of membranes water transport across the membrane is largely prohibited. The selectivity of membranes for an anion or cation is better than 90 %.

Stack of Fuel Cells in Electrodialysis

Alkaline fuel cell (AFC) is a fuel cell type which utilizes alkaline electrolyte, usually potassium hydroxide. It consumes hydrogen and oxygen producing only water, heat, and electricity. Depending on a concentration of potassium hydroxide AFC can operate at temperatures between 60 °C and 250 °C. The fuel cell reactions are as follows:

The main ionic charge carriers are OH^- ions which mitigate from the cathode to the anode. Water is formed at the anode side and has to be removed from the system in order to prevent KOH dilution. The AFC has improved cathode performance compared to acidic fuel cells due to more favorable oxygen reduction reaction kinetics. For this reason, AFC can achieve higher efficiency, i.e., higher voltage at comparable current densities than other fuel cell types. It has very long operating life time, e.g., 15,000 h have been demonstrated (Cifraín and Kordesch 2003). Furthermore, alkaline conditions allow application of nonprecious metal catalysts which could reduce significantly the material costs of this fuel cell. One of the major disadvantages of AFC is its low CO_2 tolerance due to formation of carbonates according to:

The carbonates have low solubility in strong alkaline environments forming crystals, capable of blocking of electrolyte pathways. The low CO_2 tolerance and the application of liquid electrolyte are two main hurdles for the broader commercialization of these systems. However, due to its high efficiency and high power density AFC found applications in aerospace industry, e.g., they were employed on the Appollo missions as well as on the space shuttle orbitals. For other examples of developed AFC systems please see (Seader and Henley 2006; Electroseparations, electrodialysis 2008).

Hydrogen and oxygen gases in the AFC are separated by a membrane. Usually permeable membranes also called diaphragms have been used (Gülzow 2012). A common diaphragm material up to 1980s was asbestos which due to health and environmental concerns is nowadays abandoned. Alternative materials are different polymer materials like porous polyethylene plates, nonwoven polypropylene and similar. Potassium hydroxide electrolyte wets the diaphragm pores in order to ensure its ionic conductivity. For a good fuel cell performance, the electrolyte resistance induced by diaphragm has to be minimized. This resistance is influenced by the thickness of the diaphragm material, its pore size and tortuosity, and the KOH concentration. Since liquid electrolyte causes some practical problems in AFC usage, new developments go into direction of alkaline polymer electrolyte membranes which in addition to separation possesses, similar to its acidic equivalent (e.g., Nafion), ionic conductivity in absence of liquid electrolyte. Currently there is no long-term stable membrane functioning without a liquid electrolyte phase.

Static Membrane Emulsification

Emma Piacentini¹, Alessandra Imbrogno^{1,2} and Richard G. Holdich³

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²University of Calabria, Rende, Italy

³Department of Chemical Engineering, Loughborough University, Loughborough, Leicestershire, UK

Static membrane emulsification (ME) refers to the formation of emulsion droplets by extruding the dispersed phase through the membrane pores into the continuous phase in the absence of surface shear (Fig. 1).

In the absence of shear flow at the membrane surface, the main forces acting on the droplets forming at the membrane pore level are (see Fig. 2):

- The interfacial tension (or capillary) force (F_γ) (retaining force) that represents the effect of the

dispersed phase adhesion on the pore opening. It is a function of the dynamic interfacial tension $\gamma(t)$. This force is typically assumed to be determined by the Young-Laplace equation with the continuous phase assumed to fully “wet” the membrane surface. Surfactant type and concentration greatly influence the adsorption kinetics of the surfactant and thus the dynamic interfacial tension between the two liquid phases. During the droplet formation process, the surfactant molecules adsorb to the newly formed oil-water interface reducing the interfacial tension and facilitating droplet formation. The transfer rate of the surfactant molecules from bulk solution to the newly formed oil-water interface is mainly determined by their diffusional transfer because of the absence of continuous-phase flow.

- The buoyancy force (F_{BG}) due to the density difference between continuous phase (ρ_c) and dispersed phase (ρ_d) and influenced by the volume of droplet (V_d). It is a detaching force which counteracts the interfacial tension force or capillary force.
- “Push-off” or “push-to-detach” force (G), that is, an additional detaching force applicable when there are a large number of drops at the membrane surface causing drops to deform from their thermodynamically more stable spherical shape. The contribution of this additional force is likely to be more noticeable with a regular array membrane, such as micro-sieve metallic membrane with highly uniform pore spacing and pore size

Static Membrane Emulsification,
Fig. 1 Static membrane emulsification

Static Membrane Emulsification, Fig. 2 Forces acting on the droplets forming at the membrane pore level in static membrane emulsification

compared to conventional membranes such as the Shirasu porous glass (SPG) type.

The dispersed phase flux has a great influence on the spontaneous droplet formation behavior and depends on the viscosities of disperse and continuous phases and flow velocity of the disperse phase through the membrane pore. The push-off force occurs when a critical injection rate is exceeded and all, or nearly all, of the membrane pores become active. In this condition, a large number of drops grow simultaneously at the membrane surface, and the drop diameter is bigger than the distance between the pores, so that the drops push each other off at the membrane surface. In the limiting case, when only relatively few pores are active and the distance between those pores is bigger than the size of the drops, the push-off force is zero and final drop size is defined only by an equilibrium of buoyancy and capillary forces (interfacial tension). At increasing injection rate, more and more pores will be activated and the push-off force becomes significant (Kosvintsev et al. 2008).

Another parameter affecting the droplet detachment from the pore openings is the shape of the pore openings: noncircular pore openings

encouraging the spontaneous detachment of droplets. During droplet formation from tortuous pores with a noncircular cross section, the distorted dispersed phase is spontaneously transformed into spherical droplets by interfacial tension at the membrane surface because of the minimization of the interfacial free energy of the system. This phenomenon has been observed with SPG membranes (Sugiura et al. 2001; Christov et al. 2002).

The static ME has several advantages over dynamic ME:

1. Simple experimental setup
2. Low energy input
3. Suitable for the production of less viscous and/or larger droplets with uniform size because droplet breakup due to the shear force caused by a cross-flow pump is avoided

Stem Cell

Antonella Piscioneri

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

The notion of stem cells is used to identify a peculiar kind of cells characterized by the fulfillment of two fundamental hallmarks: their ability of self-renewal and their capacity to differentiate into different cell types.

In particular, the first property refers to the possibility to undergo to numerous cell divisions without losing their stemness. This characteristic allows the preservation of the stem cell population and can be achieved through two different kinds of division: by a symmetric division in which both daughter cells are identical to the original retaining both their stem cell characteristic and by an asymmetric division in which only one daughter cell will continue to be a stem cell while the other one starts its differentiation process.

The second property is already somehow included the first and is related to their ability to give rise to specialized cells of different lineage becoming tissue- or organ-specific cells through a process identified as differentiation.

Stem cells deriving from different sources are currently classified in two different wide groups: adult stem cells and embryonic stem cells.

Adult stem cells, also identified as somatic stem cells, are present in many mature tissues and generally play a major role in protecting the system by restoring a specific function after injury as well as in maintaining tissue homeostasis. There are different sources of adult stem cells, characterized by a restricted differentiation degree (multipotent cells) which is mainly determined by the tissue of residence. The differentiation process is regulated by intrinsic genetic signals of the specific cells and environmental feature controls. The whole set of environmental factors able to support stem cell differentiation and proliferation is indicated as the “stem cell niche,” which for each tissue represent the restricted and narrow area where the adult stem cells are located. The “niche” hypothesis was proposed and developed for the first time in the hematopoietic system in mammals in 1978 by Schofield (Li and Xie 2005; Schofield 1978).

Within the human body, there are different adult stem cell niches that define the location and the physical organization of adult stem cells in the bone marrow, skin, intestine, brain, adipose tissue, dental pulp, etc. The bone marrow represents the reference tissue district for the study of the basic knowledge of adult stem cells, and it comprises both hematopoietic and

non-hematopoietic lineage of adult stem cells. The hematopoietic stem cells (HSC) give rise to the entire set of differentiated blood cells and represent a source of primary importance for their clinical application. One of the major issues related to the success of their transplantation is their unique identification through the localization of specific surface markers that are constantly pursued and updated with immense efforts devoted to this topic (Spangrude et al. 1988; Baum et al. 1992; Yokota et al. 2012).

The non-hematopoietic stem cell compartment presents mesenchymal stem cells (MSC) that can be easily isolated from the bone marrow and can differentiate, upon induction, in different cell types of the mesodermal lineage such as osteoblasts, chondrocytes, and adipocytes. The identification of the surface marker expression for the bone marrow MSCs revealed that they are positive for CD105, CD73, and CD90 and negative hematopoietic markers CD34, CD11, and CD19 and HLA-DR (Dominici et al. 2006; Satija et al. 2009).

Although the standard site for obtaining human MSC is the bone marrow, as already mentioned, MSC like cells can be obtained from a wide range of different tissues (the skin, umbilical cord blood, blood, adipose tissue, pancreas, and liver) representing a possibility to overcome the shortage of cell availability for clinical application (Al-Nbaheen et al. 2013).

Within the adult stem cell field, a groundbreaking in neuroscience was achieved in the 1990s when studies from different research groups brought to the identification of neural stem cells (NSCs). Neural stem cells can be isolated from different areas of the nervous system giving rise to both neurons and glial cells. The identification of such cells opened the possibility of finding out not only new insights in fundamental processes in neurobiology but also to study at the molecular level the process involved in neurodegenerative disease.

Embryonic stem (ES) cells derive from early-stage embryos (called blastocysts) that are 5–7 days old. The main difference with the adult stem cells is their pluripotency, meaning that they can potentially generate all kinds of

specialized cells of the body since they can differentiate into ectodermal, endodermal, and mesodermal cell types. Human embryonic stem cells grow in tightly packed colonies keeping well-defined borders at the periphery of colonies; they are characterized by the expression of a number of cell surface markers and transcription factors including stage-specific embryonic antigen-4 (SSEA-4), SSEA-3, OCT 3/4, Nanog, and the absence of hESC-negative marker SSEA-1 (Vazin et al. 2010).

Directing hESC toward a cell-specific endodermal, ectodermal, or mesodermal differentiation provides a useful tool for regenerative medicine and for pharmaceutical applications. In the literature, several cases of successful guided cell commitment toward a lineage-specific differentiation such as hepatocytes or insulin-producing β cells or functional neurons are reported. Despite this huge potential for the development of new therapeutic strategies, the challenge still remains to understand the intricate mechanisms that guide stem cell growth, cell fate decision, tissue generation, and organogenesis. This is a major issue to be considered especially in order to overcome the potentially uncontrolled growth of hESC-derived progeny and ensure safe therapeutic application. Since the generation of embryonic stem cells involves manipulation of the preimplantation stage embryo, it also erases major ethical issues that can be overcome by the introduction of induced pluripotent stem cells.

Induced pluripotent stem cells (iPS) are stem cells generated by the genetic reprogramming of somatic cells. The iPSC technology was pioneered by Shinya Yamanaka's team in Kyoto, Japan, who showed in 2006 that the introduction of four specific genes could convert adult cells into pluripotent stem cells under ES cell culture conditions. The discovery concerned the generation of embryonic-like stem cell from skin fibroblast by introducing four transcription factors (Oct 3/4, SOX2, c-Myc) that are responsible in the maintenance of pluripotency in both early embryos and ES cells (Takahashi and Yamanaka 2006; Takahashi et al. 2007; de Lázaro et al. 2014).

Although fibroblasts are the most used source for iPS, they can be derived from a wide variety of somatic cells with diverse developmental origin. These revolutionary findings opened a new scenario for a new class of stem cell therapies based on personalized regenerative medicine in which it is possible to generate patient-derived cells, covering a broad range of different applications. Patient-derived stem cells can be used for recapitulating in vitro all the landmark features that characterize a specific disease, thus representing a reliable disease modeling opening new paths for studying the pathogenic mechanism. Besides this application, they can be used for new drug development and toxicology screening.

However, many limitations exist before it can be clinically used. The use of proto-oncogenes to reach the highest efficiency of reprogramming requires permanent integration, which may create carcinogenic conditions and genomic instability. Promising results have already achieved in pre-clinical study, and new clinical challenges will be faced soon in Japan where the first human clinical study will start in 2014.

Several studies are currently ongoing in order to explore new promising alternative in iPS cell technology with the common aim of achieving new insight and promising results in tissue regeneration, most of them well summarized in a recent review of de Lázaro et al. (2014).

In the field of stem cell manufacturing practices, the introduction and realization of engineered biomaterials are promising as able to direct and promote stem cell fate decision. In this context an important role is played by the intrinsic characteristics of the material in terms of stiffness, nanostructure, degradability, and ability to promote cell adhesion and growth as well as chemical and physical properties. The ideal biomaterial for stem cell application has to provide a dynamic microenvironment that resembles as much as possible the physiological niche. In this way, cells can sense the material properties that trigger specific signals that dictate their fate accordingly (Murphy et al. 2014). Among the biomaterials applied for stem cell technology, polymeric semipermeable membranes are really encouraging. They provide the right support and lead the achievement of the

appropriate bio-interaction of desired cell responses which lead to a specific cell commitment. Besides their characteristics of selective transport properties and biocompatibility, they can be mass produced and easily sterilized. This determines a significant cut in terms of costs of the bioprocess related to stem cell applications. Noteworthy membrane surfaces can be tailored in a specific way allowing to mimic the features of the *in vivo* niche of a particular tissue district, thus stimulating specific cell responses. Taking into account these considerations, it is clear how a proper combination of stem cells and semipermeable membrane has a wide range of application in the field of stem cells, being a useful device for directing stem cells to differentiate in a specific cell type. Recent studies demonstrated the good interaction between stem cells and nanostructured biomaterials with a consequent enhancement in terms of new bone osteogenesis (Wang et al. 2014). Another example of the recreation of an osteoinductive microenvironment is provided by the use of a composite membrane scaffold made up of polycaprolactone (PCL) with hydroxyapatite (HA) that was used to successfully differentiate human mesenchymal stem cells in osteoblasts (Morelli et al. 2013). The ability of semipermeable membranes to provide the right physical and chemical signals to stem cell commitment was evidenced by using a chitosan membrane for the expansion and differentiation of progenitor liver cells toward adult hepatocytes. The chitosan membrane provided an optimal microenvironment in which the differentiation took place as demonstrated by the acquisition of parenchymal cell morphology, proper of fully differentiated hepatocytes, as well as by the ability to perform differentiated functions (Piscioneri et al. 2011). Within a membrane system, it is possible to recreate well-controlled and defined surroundings, and thus they can be used as *in vitro* platform to study both signaling pathways involved in cell fate specification and to highlight their action on damaged cells of different tissue districts (Piscioneri et al. 2015). In this section just a few examples of use of the membranes for stem cell applications are provided, but their tunable characteristics allow their employment in a wide range of applications.

Stimuli Responsive

Jinming Peng¹, Xueting Zhao², Yanlei Su²,
Hong Wu² and Zhongyi Jiang²

¹Key Laboratory for Green Chemical Technology of Ministry of Education, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

²School of Chemical Engineering and Technology, Tianjin University, Nankai, Tianjin, China

Stimuli responsive: Stimuli responsive is a phenomenon in which materials are capable of reversibly altering their properties depending on the environmental conditions or external stimuli. External stimuli typically encompass physical (e.g., temperature, photo, redox signal, or magnetic field), chemical (e.g., pH, ionic strength, or a specific molecule), or biological (e.g., viruses or bacteria) stimuli. The stimuli-responsive membrane often involves the conformational variation of sensitive units covering on the membrane surface or the pore surface, which causes the changes in physicochemical properties, pore size, and permeation flux. The stimuli-responsive membranes are playing an increasingly important part in a diverse range of applications, such as drug delivery, diagnostics, tissue engineering, biosensors, and chemical and biological separations.

Thermo-responsive membranes can adapt to environmental temperature change due to the

thermo-responsive polymer, whose temperature-dependant solubility can reversibly solubilize upon changes in temperature and lead to conformational changes: stimulated collapse by dehydration and expansion by rehydration (Lee et al. 2010). The polymers are soluble in aqueous solution below lower critical solution temperature (LCST) through hydrogen bonding with water molecules but become dehydrated and insoluble when heated above the LCST. The typical thermo-responsive linear polymers such as poly (N-isopropylacrylamide) (PNIPAAm) exhibit sharp phase transitions around 32 °C, below which the mixture of polymer and solution is miscible. The thermo-responsive membranes prepared through grafting of PNIPAAm are often utilized for drug delivery because the LCST of PNIPAAm is close to body temperature. Usually, a significant increase of permeation flux and a reduction of rejection can be observed when the temperature increases above the LCST.

The pH-responsive membranes are prepared by ionizable polymers with a pK_a between 3 and 10. Weak acids and bases like carboxylic acids, phosphoric acid, and amines exhibiting a change in the ionization state upon variation of the pH of aqueous solutions are the candidates for preparing pH-sensitive membranes. Classical monomers includes acrylic acid (AAc), methacrylic acid (MAAc), maleic anhydride (MA), and N,N-dimethylaminoethyl methacrylate (DMAEMA). The unique properties of pH-responsive polymers arise from the facile pH adjustment which induces the ionic interaction and hydrogen bonding, resulting in a reversible micro phase separation or self-organization phenomenon (Wischerhoff et al. 2010). Thus, pH-responsive polymeric systems provide the possibility for the preparation of smart functional materials which can be used for potential therapeutic applications, e.g., controlled drug delivery based on pH-triggered release. Usually, the membranes with negatively charged surface possess a higher flux at the pH lower than the pK_a of monomer than that of at the pH higher than the pK_a .

Photo-responsive membranes usually possess photo-responsive units such as azobenzene,

spiropyran, and diarylethenes in the polymer side chains, which are capable of isomerization. Structure changes in the photo-sensitive units on membrane surface lead to changes in the macroscopic properties including wettability, charge, and mass transport.

Salt-responsive membranes can adapt to environmental salt concentration (ionic strength) and are often prepared using zwitterionic polymers of polyelectrolyte. The addition of salt was found to screen the electrostatic interaction within the polyelectrolyte, resulting in conformation changes from stretched to collapsed form (Wandera et al. 2011). Usually, the porous membrane possesses higher permeation flux and low rejection under high ionic strength due to the collapse of polymer chains and the fully open pores.

Multi-responsive membranes are responsive to more than one stimulus. Membranes exhibit responses to different stimuli such as temperature, pH, and photo that are prepared based on temperature-responsive NIPAAm and pH- and photo-responsive spirobenzopyran. Membranes fabricated by using acrylic acid, NIPAAm, and cinnamoyloxyethyl acrylate exhibit four kinds of responses to pH, temperature, ionic strength, and photo stimuli.

Strip Dispersion Supported Liquid Membrane

Pietro Argurio

Department of Chemical and Environmental Engineering, University of Calabria, Arcavacata di Rende, Italy

A liquid membrane (LM) is a thin liquid film that separates two other liquid phases with which it is immiscible. There are three basic forms of LM processes: bulk liquid membrane (BLM), emulsion liquid membrane (ELM), and supported liquid membrane (SLM) (Molinari and Argurio 2009). The small membrane surface area per unit volume represents the most important drawback of BLMs, making them not attractive by a technological point of view. ELMs are characterized by a large surface area per unit source phase volume, which enhances the transport rate. One disadvantage of ELMs is the low emulsion stability, so that if for any reason the membrane does not remain intact during operation, the separation achieved to that point is destroyed. SLMs usually consist of an organic solvent impregnated in the pores of a hydrophobic microfiltration membrane (Molinari and Argurio 2011). SLM combines extraction and stripping processes into one single step, which provides the maximum driving force for the separation of a target species. SLM has many advantages over traditional separation technologies such as solvent extraction including high selectivity, low carrier and solvent consumption, high degree of concentration enrichment, and so on. Despite the abovementioned advantages, SLMs are not currently used on a large scale in the industry, since membrane stability or lifetime is, in general, far too low to assure good commercial applications. Instability of SLMs is due to the loss of carrier and/or membrane solvent from the membrane phase which has an influence on both flux and selectivity of the membrane (Kemperman et al. 1996). In addition, the flux of solute through SLM is lower because of the higher resistance of mass transfer from the presence of static membrane solution filled in microporous supports.

For solving the above difficulties and obtaining LM system with high efficiency, new configurations have been proposed. Ho (2002) and Teramoto et al. (2000) proposed a combined SLM/strip dispersion process (i.e., the strip solution was dispersed in the membrane organic phase) for the removal and recovery of target species from a feed solution. This new LM configuration has several advantages: (i) increased stability, (ii) reduced costs, (iii) increased simplicity of operation, (iv) extremely efficient stripping of the target species from the organic phase, and (v) high flux and a high concentration of the recovered target species in the aqueous strip solution. An important limitation of SLM with strip dispersion system is represented by impossibility to avoid the pollution of the aqueous solutions with membrane solution due to its dissolution in both aqueous feed and strip solutions. In this context, the choice of membrane solution with water-insoluble components is a key step.

The combined SLM/strip dispersion system can be schematized as reported in Fig. 1: a microporous hydrophobic support (e.g., polypropylene) acts as the liquid membrane support. The strip dispersion is a mixture of an aqueous strip phase, containing a stripping agent, and an organic phase containing an extractant. During the extraction process, the dispersion flows through one side of the SLM. A feed solution containing the target species is passed on the other side of the SLM.

In 2006, He et al. studied the recovery of Zn (II) ions by using the SLM/strip dispersion system. The influence of various experimental parameters on the separation of binary Zn (II) and Cu(II) ions, that is, system of great importance to hydrometallurgy and environmental protection, was investigated. Obtained results evidenced that this new configuration of LM is applicable in the separation and recovery of solutes from aqueous solutions.

Strip Dispersion Supported Liquid Membrane, Fig. 1 Schematization of the combined supported liquid membrane/strip dispersion system (elaborated from He et al. (2006))

The same LM configuration, called strip dispersion hybrid liquid membrane (SDHLM), was studied by Gu et al. (2006) for the transport and separation of Cd(II) from Zn(II) ions from aqueous media. The results evidenced that cadmium (II) can be effectively transported into the stripping solution from the feed phase by the SDHLM using tri-*n*-octylamine-secondary octanol in kerosene as carrier. The proposed system has superiority over SLMs and ELMs in terms of: (i) transport rate, since the efficient contact area between organic and stripping solution results in an extra mass transfer surface; (ii) permeability coefficient and extraction or recovery percentage of Cd(II); (iii) efficiency of uphill transport; (iv) membrane stability; and (v) no usage of high active surfactant and demulsification device.

A hollow fiber supported liquid membrane (HFSLM) with strip dispersion was tested by Li et al. (2009) in the recovery of fumaric acid from aqueous effluents. Under the optimum operating conditions, the extraction of fumaric acid was 89.5 %, and the total TOC removal reached 96.5 %. Compared with the results obtained with SLM, the extraction was enhanced by 26.6 % and the TOC removal by 9.5 %. Besides, no significant loss of the membrane phase was observed, and the stability of the HFSLM with strip dispersion system was remarkably good. A not negligible pollution of the aqueous solutions with membrane solutions was observed, so that the author concluded that further research needs to be carried out to solve this important issue.

More recently (Vilt and Ho 2009, 2011), SLM with strip dispersion has been applied to the recovery of cephalixin, an important and widely used semisynthetic antibiotic traditionally produced by a ten-step chemical synthesis. An enzymatic synthesis for cephalixin, offering several advantages over the classical route, has been developed, but it requires an in situ extraction which ensures enzyme stability. Obtained results evidenced that yield of cephalixin was increased from 32 % to 42 % when in situ removal was conducted using two hollow fiber modules and an organic membrane solution containing 10 wt. % Aliquat 336. Enzyme stability experiments showed that the organic membrane solution did

not significantly deactivate the enzyme. The final recovery of cephalixin from aqueous stripping solutions was achieved using complexing agents.

Stripping Agents: Use in Liquid Membrane System

Gerardo León
Departamento de Ingeniería Química y
Ambiental, Universidad Politécnica de Cartagena,
Cartagena, Spain

Stripping agent is used in a liquid membrane system. A stripping agent is a chemical specie

Stripping Agents: Use in Liquid Membrane System, Fig. 1 Stripping agents and transport processes: (a) HCl, type 1-facilitated transport of amines; (b) NaOH, carrier-

facilitated transport of phenols; (c) Cl^- , carrier-facilitated countertransport of amino acids; (d) SCN^- , carrier-facilitated cotransport of metallic ions

which is added to the product phase of a liquid membrane to react, in the membrane/product interface, with the target species or with the complex target species carrier, giving a membrane insoluble product or simply releasing the target species in the product phase. In order to improve the effectiveness of the liquid membrane separation processes, by maximizing both the extraction velocity (flux through the membrane phase) and the reception capacity of the diffusing species in the product phase, a stripping agent is added to the product phase. This agent quantitatively reacts, in the membrane phase/product phase interface, either directly with the diffusing species to yield a membrane insoluble product, preventing it from diffusing back through the membrane (facilitated transport type 1), or with the complex formed between the target species and a carrier (added to the membrane phase to transport that target species across the membrane from the feed to the product phase), breaking that complex, removing the target species from that complex, releasing it in the product phase, in its original form or combined with the stripping agent, and regenerating the carrier, which initiates a new transportation cycle (facilitated transport type 2) (Vitt et al. 2010).

When the reaction between the diffusing species and stripping agent leads to a membrane insoluble product, the concentration of that diffusing species is reduced to zero on the product phase, resulting in high concentration gradient across the membrane phase and, consequently, in a high driving force for the transport of the target species. When the reaction between the stripping agent and the target species-carrier releases the target species in its original form, the driving force for the transport of the target species is maintained by a concentration gradient of a second species transported in the opposite direction. The selectivity of the process can also be further enhanced by the proper choice of the stripping agent in the product phase. Figure 1 shows different stripping agents used in different membrane separation processes.

The nature and concentration of the stripping agent has an important effect on the effectiveness of the transport process (Chakraborty et al. 2010). Many chemical compounds can be used as stripping agents; their choice should be determined by the nature of the target species to be removed and recovered and by the nature of the carrier, if carrier-mediated transport is used. Though acids and bases are among the more widely used

stripping agents, many other chemical species have also been employed in the transport of many compounds by liquid membranes. A stripping agent should include the following characteristics (Gu et al. 1992):

Soluble in the product phase but insoluble in the membrane phase

If facilitation type 1, quick and quantitative reaction with the target specie in the membrane phase/product phase interface, producing the insoluble compound in the membrane phase

If carrier-mediated transport, quick and quantitative reaction and removal of the target specie from its complex with the carrier, to release the target specie in the product phase or to form the insoluble compound in the membrane phase and, in both cases, to regenerate the carrier

Strontium: Removal and Recovery by Supported Liquid Membranes

P. K. Mohapatra

Radiochemistry Division, Bhabha Atomic Research Centre, Mumbai, Maharashtra, India

Sr-90 is one of the major heat-emitting hazardous radioactive elements present in the nuclear waste which, if separated, can not only minimize the damages to the vitrified waste blocks but also can

Strontium: Removal and Recovery by Supported Liquid Membranes, Fig. 1 Structural formula of DCH18C6 and DTBuCH18C6

have many applications as power source (Schulz and Bray 1987). Membrane-based separation methods have been tested for Sr-90 recovery from radioactive wastes which largely include UF membranes (Juang et al. 2003). This method resulted in high DF values when a Sr(II) selective sorbent (such as TiO_2) in colloidal form has been used along with the filtration step (Fabiani et al. 1986). There are also reports on electrodialysis method for Sr separation (Gasser and Nowier 2004). Liquid membrane methods such as supported liquid membrane (SLM) and polymer inclusion membrane (PIM) containing a Sr (II) selective carrier such as a crown ether have been extensively investigated by different researcher groups which showed selective Sr(II) transport (Dozol et al. 1993; Mohapatra et al. 2004). Crown ethers, such as dicyclohexano-18-crown-6 (DCH18C6) and 4,4'-(5')di-tert-butyl-dicyclohexano-18-crown-6 (DTBuCH18C6, Fig. 1), have been extensively used for the selective Sr(II) transport with the later ligand being significantly more efficient due to a lesser tendency for aggregate formation (Horwitz et al. 1990). There are reports on the transport of Sr(II) using other carrier extractants such as Cyanex 272 though the transport efficiency was very poor (Kozłowski et al. 2006).

Sr(II) recovery using crown ethers from weakly acidic feeds have used bulky counter anions like picric acid or dinonylnaphthalene-sulfonic acid (DNNS) which showed transport rates for the alkali metal ions as $\text{Ba}^{2+} > \text{Sr}^{2+} \gg \text{Ca}^{2+}$. The relative extraction efficiency of Ba(II) and Sr(II) showed a reversal when the carrier solvent contained DCH18C6 or DTBuCH18C6 in 1-octanol which suggested change in the metal ion extraction mechanism at the feed-membrane interface. However, Sr recovery

Strontium: Removal and Recovery by Supported Liquid Membranes, Table 1 Sr(II) SLM transport data from acidic feeds using crown ether-based solvents

Feed composition	Membrane configuration	Solvent system	% Sr transport (24 h)	Ref.
Nuclear fuel reprocessing concentrate	Flat sheet SLM	DC18C6 in n-hexylbenzene + iso-tridecanol (modifier)	80 %	(Dozol et al. 1993)
Synthetic nuclear waste containing 1 M HNO ₃ and 2 M Al(NO ₃) ₃	Flat sheet SLM	DTBCH18C6 in 1-Octanol	65 %	(Rawat et al. 2006)
3 M HNO ₃	Flat sheet SLM	DTBCH18C6 in 1-octanol + toluene (modifier)	~50 %	(Raut et al. 2009)
3 M HNO ₃	Flat sheet SLM	DTBCH18C6 in 80 % NPOE + 20 % n-dodecane	>98 %	(Raut et al. 2012)
Synthetic high-level waste	Hollow fiber SLM	DTBCH18C6 in 80 % NPOE + 20 % n-dodecane	>94 %	(Kandwal et al. 2012)

studies from acidic feeds using 1-octanol or analogous diluents have shown nonquantitative Sr (II) transport due to a competing acid cotransport process. Though the ionic size of H⁺ ion is much smaller as compared to the cavity size of the crown ether, it is the hydronium ion which is responsible for the competitive complexation and transport of acid. The nature of the aqueous feed with lower nitric acid concentration and higher nitrate salts have been the key to a far improved Sr transport (Table 1). The nature of the diluent also found to play a significant role in Sr(II) transport by suppressing nitric acid cotransport. Use of diluent mixtures for lower acid co-extraction was successfully demonstrated in solvent extraction studies. On the other hand, supported liquid membrane transport studies showed rapid Sr(II) transport with a much lower acid cotransport initially, though the trend showed a reversal subsequently with significantly slowed down Sr(II) transport rates and even a back transport from the receiver to the feed compartment with a resultant transport efficiency of little over 50 % (Raut et al. 2009). On the other hand, a 2-nitrophenyloctyl ether (NPOE)-based solvent containing DTBuCH18C6 has been found to be highly efficient for the quantitative Sr(II) transport even at feed acid concentration as high as 3–4 M HNO₃. The flat sheet-supported liquid membrane system containing the crown ether – NPOE solvent – showed near quantitative transport of Sr(II) which has led to subsequent development of a hollow fiber-based SLM system for >95 % Sr

(II) transport from a synthetic radioactive waste feed solution (Kandwal et al. 2012).

PIMs containing crown ethers (Mohapatra et al. 2004) and calixarenes (bis-amide or bisester containing calix[4]arenes) have been found to be quite effective for Sr(II) recovery from acidic feeds, and dinonylnaphthalenesulfonic acid (DNNS) was found to positively influence Sr(II) transport when used along with the calixarenes (Arena et al. 1998).

Styrene-Grafted Film

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

Styrene is an organic compound with the chemical formula $\text{C}_6\text{H}_5\text{CH}=\text{CH}_2$. Styrene is also known as

Styrene-Grafted Film, Fig. 1 Chemical structure of styrene

vinyl benzene and phenylethene. Due to the presence of vinyl group, styrene can easily be polymerized to polystyrene. Styrene can also be used as precursor for several copolymers and also can be used for graft polymerization or grafting (see graft polymerization) (Fig. 1).

Styrene is of commercial importance and used in the production of commercially significant products including polystyrene, styrene-butadiene rubber (SBR), acrylonitrile butadiene styrene (ABS), styrene-butadiene latex, styrene-isoprene-styrene (SIS), styrene-ethylene/butylene-styrene (S-EB-S), styrene-divinylbenzene (S-DVB), styrene-acrylonitrile resin (SAN), and unsaturated polyesters. These materials are used in rubber, plastic, insulation, fiberglass, pipes, automobile and boat parts, food containers, and carpet backing.

The presence of the vinyl group allows styrene to graft onto base polymer matrix. Styrene-grafted films could be produced by grafting onto ready-made polymer films, or films can also be prepared after grafting process depending upon the nature of base polymer and the degree of grafting (Sherazi et al. 2008; Hwang et al. 2015). Another advantage to graft styrene monomers is that it contains benzene ring which is readily amenable to some application based functionalization such as sulfonation, halomethylation, (Gubler et al. 2005; Varcoe and Slade 2005) etc.

Many of the polymers have been investigated for the grafting of styrene and followed by

Styrene-Grafted Film,**Scheme 1** Styrene grafting onto polymer

sulfonation to develop membranes for fuel cells applications. Almost all commercially available fluorinated polymers, such as polytetrafluoroethylene (PTFE) (Ismail et al. 2005), Teflon-FEP (Saneto et al. 2005), fluorinated ethylene propylene copolymer (FEP) (Nasef et al. 2000), tetrafluoroethylene perfluoro(propyl vinyl ether) copolymer (PFA) (Cardona et al. 2002), polyvinylidene fluoride (PVDF) (Elomaa et al. 2000), ethylene-tetrafluoroethylene copolymer (ETFE) (Scott et al. 2000), polychlorotrifluoroethylene (PCTFE) (Zhao and Jin 1988), etc., were reported to be used for grafting with styrene. Styrene-grafted films have also been developed using polyethylene (Sherazi et al. 2008, 2009, 2013) as base polymer. Styrene-grafted and sulfonated poly(ethylene terephthalate) films were also studied as bioactive polymers to produce a “biointegrable” artificial anterior cruciate ligament (ACL) (Ciobanu et al. 2006). The scheme of styrene grafting onto polymer to produce styrene-grafted film can be represented by Scheme 1.

Grafting can be initiated by various methods including chemical initiator, radiation technique, etc. (see graft polymerization).

Submerged Biocatalytic Membrane

Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Submerged membrane bioreactor (SMBR) systems have mostly been used to treat industrial wastewater, domestic wastewater, and specific municipal wastewater, where stringent discharge standards were required in order to make it usable. It is expected, however, that membrane bioreactors systems will increase in capacity and broaden in application area due to future, more stringent regulations and water reuse initiatives. In the early 1990s, MBR installations were mostly constructed in external configuration, in which the membrane modules are outside the bioreactor and biomass is recirculated through a filtration loop. After the mid-1990s, with the development of SMBR system, MBR applications in municipal wastewater extended widely. The application of submerged membrane bioreactor is mainly for the waste water treatment whilst for other possible application like recovery/production of value-added component, in biotechnological application, in food processing, etc., a few examples are still known. The development of submerged biocatalytic membrane reactor (SBMR) containing the biocatalyst immobilized within the membrane for these production systems has been reported.

The enzymatic biphasic processes are of increasing use in the production, transformation, and valorization of different biomass-based raw materials. Important applications have been developed in the fields of food, drinks, fine chemicals synthesis, pharmaceutical grade products, and cosmetics or even for clean and green

environmental purposes. Most of the time, the reactions and separation of the product are carried out in a classical side stream enzymatic membrane bioreactor.

The conventional side stream enzyme membrane bioreactor (MBR) could be used as a continuous process in which enzymes are separated from end products with the help of a selective membrane layer. In two-phase bioconversions membrane acts as a support for the interface between two distinct liquid phases. The membrane not only separates the phases, but also provides interfacial contact area and, together with the enzyme, acts as an interfacial catalyst. A complete retention of the enzyme within the system is an important requirement for a successful continuous operation of membrane bioreactor with immobilized enzyme. Upon this retention, the enzyme becomes confined to a defined region of the membrane reactor, where reaction with the substrate occurs. Two compartments partitioned by enzyme-loaded membrane, promote reaction and product separations simultaneously.

The concept of the two separate phase membrane reactor has been explored using the enzyme-loaded membranes in the submerged configuration (Chakraborty et al. 2012). The submerged membrane promotes both catalytic and separation processes. The hydrolysis of triglycerides into fatty acids and glycerol has been used as a model reaction to study and optimize the submerged enzyme-loaded membrane performances. The work has been focused on the study of the enzyme immobilization within the submerged membrane module, evaluation of the performance of the submerged enzyme-loaded membrane as a function of physical chemical and fluid dynamics conditions, testing of the submerged membrane reaction system with real fried cooked oil.

Submerged flat-sheet module

Submerged (immersed) membrane (SM) is an original idea, representing cheaper alternative to conventional membrane modules employed in cross-flow system. SM design involves placing flat or capillary membranes directly in the tank, usually vertically (capillary can also be laid horizontally). The air (or other gas) is supplied from the bottom of the tank. Very small transmembrane pressure (below 1 bar) is generated hydrostatically but often enhanced by a small vacuum. Although the permeate flux is smaller (up to 35 LMH)

compared with the cross-flow, which requires a larger membrane surface area, but then power consumption is significantly lower. In conventional cross-flow systems, the feed flows tangentially to membrane surface to reduce the concentration polarization or to remove cake. Therefore, conventional (cross-flow) membrane system solutions consume large amounts of energy to maintain the flux, which often exceeds 10 kWh/m^3 for circulation. Moreover, in a typical membrane modules (especially capillary, spiral, and flat plates), the requirements as to the materials combined with a complicated structure cause additional serious costs. Another important parameter is the right choice of membrane material (chemical compatibility) as well as appropriate pore size distribution. Membranes should have the narrowest pore size distribution as possible. There is also a rule that the smaller the pore size, the smaller is the tendency for the inner pore blocking, which may be irreversible.

In immersed membrane systems (Fig. 1), the innovative approach is to take use of the newer concepts such as critical flux theory or turbulences generated by gas sparging. The role of gas sparging in submerged membrane is similar to cross-flow (to facilitate turbulences) but much more cheaper. The gas flowing between the capillaries or sheets causes reciprocal and gentle movement that keep the flow of permeate flux with lower amount of energy (below 3 kWh/m^3).

Submerged Membrane,

Fig. 1 Submerged membranes

In some cases the costs for periodic backflushing and/or cleaning of membranes (CIP cleaning in place) have to be added. This requires the use of additional expenditure on chemicals and to dispose and further complicates the process (automation) and causes the system downtime. However, during ultrafiltration, only stopping of the plant, is sufficient for polarizing layer that spontaneously be dissolved in the core (bulk) due to back-diffusion. In the microfiltration process, the gas sparging gently moves the membranes which cause crushing of the filter cake layer. In individual cases, where possible, it is used in addition to other methods of cleaning the membranes, such as flushing of the liquid phase (penetration) or gas phase and chemical cleaning of various intensities. Thus, the best adapted strategies for cleaning the submerged membranes should be adapted for the specific case. The chemically supported backflushing is used daily, chemical cleaning of high concentration once per week, or intensive chemical cleaning annually.

The main advantages of SM system should therefore be low investment costs, which result from a simple and reliable design, easy installation, and compact size (small footprints). Low operating costs result from the low power consumption, low maintenance costs, and ease of use and repairs, through continuous monitoring. In addition to these economic advantages, submerged membrane also features high performance and high efficiency. Submerged membranes can be easily used for retrofitting (expansion and modification) of existing systems. Thanks to its numerous advantages, submerged membranes found itself since its inauguration popularity in the following areas:

- Food industry (beverages, alcohols, dairy)
- Chemical industry
- Electronic
- Mechanics
- Laundries
- Bathing
- Photo
- Medicine
- Agriculture (livestock and aquaculture)
- Wastewater treatment

Immersed Membrane Bioreactor (IMBR)

Submerged membrane bioreactors (SMBs) are a type of membrane bioreactor MBR, where two processes, i.e., the chemical reaction and separation, took place simultaneously to produce a synergistic effect. The first idea of membrane reactor connection was founded at Rensselaer Polytechnic Institute, Troy, New York (Smith et al. 1969). The first use of MBR to the activated sludge in wastewater treatment plants has been done by Dörr-Oliver, Inc., Milford, Connecticut, USA (Hardt et al. 1970). After several years this idea was popularized in Japan and developed by Yamamoto et al. (1989) and the company KUBOTA, which introduced further integration in the form of flat sheet membranes immersed directly in the reactor tank. The first application of submerged membrane reactor is the sewage system, which is considerably simplified comparing to conventional (see Fig. 1). The rapid development of SMB applications has been caused by the following: (1) legislation, (2) local water scarcity, (3) return on investments, (4) environmental impact, and (5) public and politician acceptance (Judd 2011).

Flat plate or capillary membranes are usually immersed vertically in a tank where feed is

Submerged Membrane Bioreactor, Fig. 1 Comparison between (a) conventional wastewater plant and (b) SMB wastewater plant

Submerged Membrane Bioreactor, Table 1 Comparison of two types of membrane bioreactors manufactured by ZENON[®], i.e., sidestream tubular MBR and submerged SMB (Cote and Thompson 2000)

	Membrane bioreactor MBR	Submerged membrane bioreactor SMB
Model	Permaflow Z-8	ZeeWeed ZW-500
Surface area [m ²]	2	46
Permeate flux [l/m ² h = LMH]	50–100	20–50
Pressure [bar]	4	0,2–0,5
Airflow rate [m ³ /h]	–	40
Energy [kWh/m ³]	4–12	0,3–0,6

delivered. The capillary membranes can also be arranged horizontally (see Table 1). The permeate is discharged by means of collectors on the outside of the tank under hydrostatic pressure or light vacuum using a pump. The integration of membrane and reactor introduces well-known benefits, such as accelerating the kinetics of the process and increasing its efficiency. Continuous removal of the products from the reaction space and the

retention of the substrates shifts the equilibrium to the right (toward product), thus increasing the efficiency of the process. In this case, the membrane also helps to avoid adverse reactions, which can lead to transient products. Submerged membrane bioreactors are much more cost-effective when compared to conventional cross-flow membrane modules (see Table 1).

The role of the costly cross-flow has been replaced in SMB by mild hydrodynamic conditions, where gas sparging is often used (see Fig. 2). For this purpose, the gas is supplied from the bottom so as to flow over the surface of the membrane. The role of gas sparging in submerged membrane bioreactors is twofold, i.e., hydrodynamics and mass transfer enhancement. The gas flow increases the turbulence and produces smooth movements which help to remove the filter cake from the membrane surface during microfiltration and reduces the concentration polarization layer during the ultrafiltration. In the case of aerobic bioreactor, the gas may simply be air. In the case of anaerobic bioreactors, inert gas is used to assist desorption of gaseous products from the liquid.

The SMB is most often used to remove xenobiotic and various biological nutrients, i.e., substances such as carbon, nitrogen, and phosphorus,

for the treatment of municipal, industrial wastewater, water treatment, and recycling of different process waters. SMB is also used for the purification of groundwater and surface waters (Yimaza et al. 2006), as well as waters for irrigation. Industrial sectors that use the SMB are food and beverages, where high loads of chemical oxygen demand must be reduced. Other sectors of the industrial wastewater treatment plants are in the textile, electronics, pharmaceutical, chemical,

metal finishing, automotive, petrochemical, and pulp and paper. SMB reactors are also used on offshore oil and gas platforms and on barges, ships, boats, and yachts (Table 2).

SMB has a lot of advantages compared with conventional systems, in particular activated sludge (ASB Yilmaz et al. 2006). The use of microorganisms floating freely allows for easier access to the substrate (a few microns) and thus a faster bioconversion compared with ASB (several hundred microns of flocks in activated sludge). SMB can operate effectively in all dilute solutions even below threshold values for ASB that is 0.01 kg COD/(m³ day). This is because the kinetics of bioconversion in the SMB is faster since it is limited only by chemical reaction, which is much faster compared to mass transport in the activated sludge. Thus, using SMB is cheap and easy, because it helps minimize capital and operating expenses. Low energy costs are associated with the use of energy-efficient method of removing a filter cake (in MF) or a polarizing film (in UF) from the surface of the membrane, such as gas sparging in moderate hydrodynamic conditions. Low capital cost based on a simple and very compact design, which consists of closely arranged membranes directly immersed in the tank bioreactor design with compact stacked membranes that are placed directly in the reactor. In addition, the SMB does not require settlers, thus occupying less space (footprint) in sewage treatment plants, which, in case of conventional solutions, can be very burdensome to the environment, particularly in the open air. Using SMB ensures greater bioconversion kinetics and shows better flexibility and versatility of bioconversion. SMB bioreactor has many other

Submerged Membrane Bioreactor, Fig. 2 Gas sparging around the capillary membranes in the laboratory stand

Industrial plants	400	204	127
Municipal plants	1138	170	204

important features such as high-performance density and ease of membrane replacement and disposal of waste, ease of automation, and ease of design and scale-up. SMB systems are easy to operate and maintain, allow for remote monitoring and control, and are much easier to control by the operator. These characteristics predestine the SMB to development and retrofitting existing facilities. The global market is growing rapidly at a 20 % annual rate value that is estimated to exceed 1bln \$ in 2012 (Judd 2011).

The main suppliers of bioreactors with submerged membranes are:

1. KUBOTA[®], MICRODYN-NADIR[®], WEISE[®], TORRAY[®], KUBER[®] (flat sheet membranes)
2. ZENON[®], MITSUBISHI RAYON[®], SIEMENS-MEMCOR[®], KOCH-PURON[®], ASAHI KASEI[®], KMS KOREA LENNTECH BV[®], TRIQUA[®], TORRAY[®], COLLOIDE[®], MEMSTAR[®], ASIA GIANT[®], MOTIMO[®] (hollow fiber)
3. NORIT[®] (tubular)

Sugarcane Juice, UF Application of

Malini Balakrishnan

The Energy and Resources Institute (TERI),
New Delhi, India

About 80 % of the world's sugar (sucrose) production comes from sugarcane. The sugarcane is milled to extract the juice, which is then screened to remove bagasse particles, the fibrous residue from sugarcane milling. The screened juice is clarified, concentrated in multiple effect evaporators, and the syrup crystallized to obtain sugar crystals. The residual syrup (molasses) is rich in sugars and minerals; it is used as a sweetener, in cattle feed, and in production of ethanol and biochemicals. Figure 1 shows the production process.

The raw juice contains colorants and color precursors (3–5 % soluble solids), besides organic nonsugars such as proteins, polysaccharides, and waxes (0.85–1.45 % soluble solids) (Chen and Chou 1999). Ultrafiltration (UF) and microfiltration (MF) can be used for improving juice clarification (Fig. 2), which is a key step to remove nonsugar impurities. For clarification, the juice is heated to about 70 °C and treated with Ca(OH)₂ (for raw sugar) or Ca(OH)₂ and SO₂ (for “plantation white” sugar). This mixture is boiled and the precipitated impurities settled using a suitable flocculent. The clarified juice so obtained is dark brown (or brownish yellow) and somewhat hazy due to the presence of colloidal and dissolved macromolecular components; furthermore, it contains fine bagasse particles. These impurities lead to sucrose loss in molasses (thereby reducing sugar yield) and poor-quality sugar crystals.

Sugarcane Juice, UF Application of, Fig. 1 Schematic of sugar production process adapted from Ghosh and Balakrishnan, 2003)

Sugarcane Juice, UF Application of, Fig. 2 UF of clarified sugarcane juice (20kD polyethersulfone membrane; trials conducted in a sugar factory in India) (a): Retentate (b): Feed (c): Permeate

UF (or MF) of the clarified sugarcane juice enhances nonsugar removal. The filtered juice has higher purity, lower boiling times, and higher crystal growth rates. UF also reduces the calcium content in the permeate, thus controlling evaporator scaling. There are two main challenges in this application:

- Processing large volumes of hot juice in short time: even a small factory can process up to 100 m³/h of juice. High flux coupled with high concentration factors (to minimize sugar loss in the retentate) is thus essential. The clarified juice temperature is typically >90 °C. Filtration of the hot juice offers advantages of higher flux, reduced feed viscosity (making pumping easier), and minimizing microbial contamination. As sugarcane juice is prone to degradation and color formation with storage, rapid processing is required.
- Suitable membrane properties: membrane fouling (mainly due to high molecular weight polysaccharide component in the juice) is a major operational limitation. Besides, the juice composition changes considerably over the sugarcane crushing season of 6–10 months' duration. The variations originate both from

sugarcane properties (e.g., differences in varieties, soil and agroclimatic conditions, postharvest injuries to the sugarcane) and mill operation conditions (e.g., changes in milling and clarification parameters). The membrane should therefore be able to handle the variations in feed properties, be thermally and mechanically stable, and be resistant to small amounts of abrasive materials (e.g., sand) which can concentrate in the recirculation loop. It should also be easily preserved during the off-season (2–6 months, when the factory is closed for maintenance).

Both polymeric and ceramic membranes in the 3 kD to 0.2 μm range have been investigated. Ceramic membranes are more suitable with better chemical and physical stability; they can also be stored dry. Because of their higher cost, trials with ceramic membranes are limited and more demonstrations are reported with polymeric membranes. Finally, though several factory trials on UF and MF of sugarcane juice have taken place since 1990, the economic viability of the process is not established.

Sulfonated Aromatic Polymer

S. M. Javaid Zaidi^{1,2} and Kripal S. Lakhi¹

¹Australian Institute for Bioengineering and Nanotechnology, The University of Queensland, Brisbane, QLD, Australia

²King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

Sulfonated aromatic polymers (SAP hereafter), as the name suggests, are polymers obtained by sulfonation of the aromatic polymers. Membranes

fabricated from the sulfonated aromatic polymers are SAP membranes. Sulfonation process imparts a number of desirable and useful properties such as high ionic conductivity, better hydrophilicity, and relatively higher solubility of the parent aromatic polymer (Vona and Knauth 2013). Sulfonation introduces sulfonic acid functionality by simple electrophilic aromatic substitution thereby enabling enhanced proton transport necessary for high proton conduction in fuel cells applications (Vona and Knauth 2013). Additionally, presence of sulfonic acid groups converts the parent polymer into ionomers without polymer chain degradation and increases its glass transition temperature (Zaidi 2003; Xing and Kerres 2006). The number of sulfonic acid groups, also called degree of sulfonation (DS in short), can be controlled by controlling the sulfonation reaction parameters, such as temperature and time (Meyer and Schrickel 2013; Zaidi 2003). A high degree of sulfonation results in swelling of the membrane which is manifested in the form of lower or reduced mechanical stability (Meyer and Schrickel 2013). Sulfonation is the best technique to make the polymer soluble in appropriate solvents especially good for thermoplastics which are not soluble in any solvents, such as polyether ether ketone. Exposing the sulfonated polymers to temperatures higher than 300 °C results in degradation of the polymer after which sulfonic acid groups are released from the polymer backbone (Meyer and Schrickel 2013; Zaidi 2003). Incorporation of sulfonic acid groups into the polymer backbone widens the scope and application of parent aromatic polymer. The applications of SAP includes such diverse and important areas as fuel cells, electrodialysis, ion-exchange resins and catalysts, surgical instruments, implant, and wound healing and dressing to name a few (Vona and Knauth 2013). SAP membranes are widely viewed by the scientific community as a possible replacement of the existing state of the art Nafion[®] membrane developed by Du Pont. Some of the key and important properties of SAP that are of interest to the scientific community and industry include ionic conductivity, water uptake, permeability, increased solubility, and mechanical stability (Vona and Knauth 2013; Zaidi 2003;

Sulfonated Aromatic Polymer, Fig. 1 Structures of common sulfonated aromatic polymers

Othman et al. 2007). Besides, SAP membranes are economical and easy to introduce sulfonic acid groups by a simple method.

Several variations of SAP based membranes such as sulfonated poly (ether ether) ketones (SPEEK), sulfonated polyphenylsulfones (SPPSU), sulfonated polyethersulfone (SPES), etc., to name a few, have been investigated as polymer electrolyte membrane in polymer fuel cells. Of these, the most studied and highly promising SAP is the polymer based on poly (ether ether ketones) or PEEK. Sulfonated PEEK (or SPEEK) is known to have high proton conductivity and high thermal and mechanical stability. High level of sulfonation makes polymer membranes amorphous and reduces its mechanical strength, making membranes brittle (Zaidi 2003; Tohidian et al. 2013). Structures of some common sulfonated aromatic polymers are shown in Fig. 1.

Sulfonation of aromatic polymer membranes can be achieved by two different approaches namely postsulfonation approach and direct sulfonation of the aromatic polymers. In this method, the aromatic polymer is first sulfonated to the desired degree and then membranes are fabricated from it. In the other approach, the membranes are first fabricated and then sulfonation is carried out on the membrane. In this case the surface of the membrane is modified, while in the other case the whole of the polymer is modified by sulfonation. However, the latter approach is most commonly used than the former for a variety of reasons. Each of the two approaches has its own advantages and disadvantages. In postsulfonation, it is difficult to control and is limited by the solubility of the polymer as it is carried out in homogeneous medium, whereas direct sulfonation consumes

large quantity of solvent and often separation of sulfonated polymer from the reaction mixtures poses a challenge. The choice of the approach is dictated by the properties and functionality desired in the SAP membranes (Vona and Knauth 2013; Meyer and Schrickel 2013; Zaidi 2003; Tohidian et al. 2013).

Sulfonation can be accomplished using a variety of sulfonating agents such as fuming sulfuric acid, concentrated sulfuric acid, chlorosulfonic acids, and sulfur trioxide (both in liquid and gaseous forms) (Vona and Knauth 2013; Meyer and Schrickel 2013; Zaidi 2003). These agents are classified as strong and mild agents and consequently affect the final yield and extent of sulfonation. As with any organic reaction, sulfonation process is also marred with unwanted side reactions, cleavage of chain to mention a few if not properly carried out especially with fuming sulfuric acid (Meyer and Schrickel 2013; Zaidi 2003). Each of these sulfonating agents has some adverse effect on the sulfonation process. Use of fuming sulfuric acid generates lots of water as a by-product thereby promoting the reverse reaction, i.e., desulfonation. The generation of HCl as a by-product limits the use of chlorosulfonic acid as a sulfonation agent as the generated acid must be neutralized. Some milder forms of sulfonating agents are trimethylsilyl chlorosulfonate, acetylsulfate, or a complex of SO_3 with amine or trialkyl phosphates also commonly used (Meyer and Schrickel 2013; Zaidi 2003). Choice of the sulfonating agent depends on the kind and type of the aromatic polymer and its molecular weight. Utmost care should be taken when sulfonation reaction is carried out to avoid these side reactions.

Sulfonated Block Copolymer Membrane

S. M. Javaid Zaidi^{1,2} and Kripal S. Lakhi¹

¹Australian Institute for Bioengineering and Nanotechnology, The University of Queensland, Brisbane, QLD, Australia

²King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

When two different monomers couple in all possible ways, it gives rise to what is known as a copolymer. Depending on the coupling pattern, copolymers are of following three types: random copolymer, block copolymer, and graft copolymer. In block copolymer, two separate chains (or blocks) of two monomers A and B are linked together as shown in Fig. 1. A typical structure of a multiblock copolymer is shown in Fig. 2.

It is well established in literature that sulfonated polymer membranes have superior properties such as high proton conductivity, higher glass transition temperature, and higher mechanical, thermal, and chemical stability as compared to non-sulfonated or parent polymeric membranes. It is also well known that a sulfonation process introduces sulfonic group functionality which is the main reason for high performance of these sulfonated membranes. Chemical modification of polymeric materials by treatment with a variety of sulfonating agents has given birth to a host of sulfonated polymeric membranes such as sulfonated polyimides, poly(ether ether ketone)s (PEEK), poly(ether sulfone)s (PES), poly(phenylene sulfide) (PPS), etc. with improved properties. Sulfonated polymer membranes however have their own disadvantages. Sulfonation of polymers is prone to side reactions resulting in cross-linking. Additionally, due to the inherent insolubility of sulfonated polymers, the nature of the solution changes from homogenous to non-homogenous as a result of sulfonation process (Meier-Haack et al. 2005). High degree of sulfonation is essential for higher proton conductivity but it causes swelling and a consequent loss of mechanical strength (Meier-Haack et al. 2005; Yeo et al. 2012; Lee et al. 2013a). The aforementioned problems can be overcome partially if not completely by using a sulfonated block copolymer. The unique feature of sulfonated block copolymer is the existence of micro-phase separation since the two blocks are chemically different and incompatible while covalently bonded to each other. The micro-phase separation is a function of the chemical nature of the different blocks and/or length of the blocks. The presence of high density of sulfonic groups on the hydrophilic side results in a well-connected phase-separated ion transport path which enhances proton conductivity without affecting physical properties (Lee et al. 2013a). Polystyrene is an example of a block copolymer which exhibits phase-separated

Sulfonated Block Copolymer Membrane, Fig. 1 Typical coupling pattern in a block copolymer

Sulfonated Block Copolymer Membrane, Fig. 2 General structure of a typical multiblock copolymer: sulfonated poly(arylene ether amide) multiblock copolymer

morphology (Meier-Haack et al. 2005). This morphological feature of block copolymers is most desirable especially in electrochemical applications such as in direct methanol fuel cells (DMFC) and in water treatment. Many studies dealing with sulfonated multiblock copolymers with ion exchange capacities (IEC) ranging from 4.1 to 5.6 meq/g for fuel cells applications have been reported, for example, sulfonated polymer obtained from 4,4'-dichlorodiphenyl sulfone (SDCDPS), and hydroquinone shows IEC value of 4.1 meq/g. Another interesting sulfonated block copolymer obtained from 4,4'-dichlorodiphenyl sulfone and bis(hydroxyphenyl)fluorene shows IEC value of 4.5 meq/g (Takamuku and Jannasch 2012). It is also reported that sulfonated multiblock copolymer membranes have higher proton conductivity at high temperatures and low relative humidities (RHs) as compared to sulfonated polymer membranes (Meier-Haack et al. 2005; Yeo et al. 2012; Takamuku and Jannasch 2012). Sulfonated block copolymer membranes also find application in water treatment for removal of ionic pollutants from wastewater where block copolymer comprising of polystyrene sulfonate (PSS) and hydrogenated polyisoprene (hPI) has been used for membrane fabrication (Yeo et al. 2012). Reverse osmosis (RO) and nanofiltration are currently the most widely used technique for water treatment, where the use of sulfonated block copolymers has been investigated to improve the mechanical integrity and enhance water permeability. In a recent report, sulfonated block copolymer comprising of polystyrene sulfonate (PSS) and hydrogenated polyisoprene (hPI) blocks has been

employed as a nanofiltration (NF) membrane with excellent results for the removal of metal ions such as copper, cadmium, and nickel ions (Yeo et al. 2012). It is believed that (hPI) chains perform a dual role of providing flexible support matrix and induce thermodynamic incompatibility with the PSS chains. This helps in controlling the self-assembly of structures in the nanometer scale (Yeo et al. 2012). Additionally, these nanostructured membranes allow higher water flux as compared to conventional RO membranes due to sulfonated block copolymers (Lee et al. 2013b).

Sulfonated PEEK (SPEEK)

Monica Pica

University of Perugia, Department of
Pharmaceutical Sciences, Perugia, Italy

Sulfonated poly(ether-ether-ketone) (SPEEK) is a fluorine-free ionomer: each repeat unit consists of an aromatic backbone of 1,4-disubstituted phenyl groups separated by ether (–O–) and carbonyl (–CO–) linkages, with the –SO₃H group generally bonded to the oxy-phenylene-oxy unit (Fig. 1).

Poly(oxy-1,4-phenylene-oxy-1,4-phenylene-carbonyl-1,4-phenylene), known as PEEK, is a relatively new semicrystalline polymer, first appearing in the literature in the early 1980s (Rae et al. 2007), with high melt and glass transition temperatures ($T_m = 340\text{ }^{\circ}\text{C}$, $T_g = 143\text{ }^{\circ}\text{C}$) and melt processable. PEEK exhibits high thermal stability, toughness, and chemical and mechanical resistance.

Sulfonation of PEEK can be achieved by postsulfonation reaction or polymerization of sulfonated monomers and enhances hydrophilicity and solubility in polar solvents while providing acidity and proton conductivity.

The PEEK postsulfonation can be performed in concentrated sulfuric acid, chlorosulfonic acid, by pure or complexed SO₃, by acetyl sulfate, and methane sulfonic acid, although the low solubility of PEEK complicates the reaction. PEEK sulfonation in sulfuric acid is an electrophilic substitution reaction, in which the sulfonating agent reacts with the hydroquinone segment of the polymer chain activated by the ether linkages. The degree of sulfonation (DS), which can reach 1.0 as maximum value, can be controlled by changing the

reaction time, temperature, and sulfonating agent/PEEK ratio (Fathime et al. 2007). Modified PEEKs, containing a lactonic group (PEEK-WC, WC = Cardo group), are amorphous polymers and soluble in many organic solvents so that they are more suitable for sulfonation reaction, which is carried out at room temperature and at shorter times with respect to traditional PEEK (Fontananova et al. 2010).

The direct synthesis of SPEEK offers some advantages with respect to postfunctionalization, such as: (1) a better control of the concentration and the position of the sulfonic group (e.g., *meta*-, *para*-, and *ortho*-); (2) avoiding cross-linking and other side reactions, resulting in better thermal stability and mechanical properties (Gil et al. 2004); and (3) the possibility to control the distribution of the sulfonic groups along the polymer backbone, thus obtaining block polymers.

The solubility of PEEKs in polar aprotic solvents, such as DMF, DMAc, DMSO, and NMP, offers a convenient process for the fabrication of membranes by solution casting (Xing et al. 2004). SPEEK membranes are studied as alternative to perfluorosulfonic acid membranes (PFSA) in polymer electrolyte membrane fuel cells, due to their good mechanical properties, thermal stability, and proton conductivity.

Water uptake of SPEEK membranes increases with increase of the ion exchange capacity (I.E. C. = meq of –SO₃H groups per 1 g of dry membrane) and affects mechanical properties and proton conductivity, which also depends on the presence of well-connected hydrophilic pathways for protons. In order to get the best compromise between high conductivity, limited water uptake and good mechanical properties, several approaches are possible: cross-linking of high sulfonated ionomers, block copolymers, and composite membranes (Iojoiu et al. 2005). SPEEK

Sulfonated PEEK (SPEEK), Fig. 1 Repeat unit structure of SPEEK

membranes showed also a methanol permeability lower than that of PFSA and they are promising for applications in direct methanol fuel cells (Fontananova et al. 2010).

Sulfonated PEEK-WC (SPEEK-WC)

Enrica Fontananova
Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The sulfonated PEEK-WC (SPEEK-WC) is the sulfonated derivative of an amorphous polyetheretherketone called PEEK-WC or poly(oxa-p-phenylene-3,3-phthalido-p-phenylene-oxa-p-phenylene-oxy-phenylene) (Zhang et al. 1987) (Fig. 1).

PEEK-WC has a lactonic group, called cardo group (WC in the polymer name means with cardo), which prevents the crystalline organization of the polymer chains; as a consequence,

PEEK-WC is amorphous, and it is suitable for the preparation of membranes by solubilization in solvents with medium polarity (e.g., chloroform, dichloromethane, dimethyl sulfoxide, dimethylacetamide, dimethylformamide, 1-methyl-2-pyrrolidinone, etc.) and casting. On the contrary, the “classical” PEEK (Fig. 1) is semi-crystalline and insoluble in organic solvents. PEEK-WC has a high glass transition temperature ($T_g = 222\text{ }^{\circ}\text{C}$) and very good chemical, thermal, and mechanical stability.

Moreover, PEEK-WC properties can be modified by introducing specific chemical groups on the polymer chain. The reaction with chlorosulfonic acid or concentrated sulfuric acid already at room temperature introduces a sulfonic group on the aromatic ring giving a polymeric material (SPEEK-WC) with ion exchange capacity (Fig. 1) (Trotta et al. 1998). The degree of sulfonation (DS) of the SPEEK-WC can be modulated by changing the reaction time and/or temperature.

The reaction is carried out in homogenous phase and in shorter times compared to that of the traditional PEEK. For example, the reaction of PEEK with concentrated sulfuric acid at room temperature for 192 h gives a polymer with $DS = 0.85$ (Nunes et al. 2002), while for PEEK-WC the same DS can be obtained by reaction in 4 h (Drioli et al. 2004).

Sulfonated PEEK-WC is a promising non-fluorinated material for application in polymer electrolyte membrane fuel cells (PEMFCs), suitable for the preparation of membranes by casting and solvent evaporation. The sulfonation level of the polymer influences the membrane properties, in particular the ion exchange capacity and the proton conductivity, which both improve with increasing DS.

Moreover, polymeric SPEEK-WC membranes with high performance in terms of proton conductivity were recently obtained by optimizing the membrane preparation conditions (type of solvent, temperature, and post-treatment) which strongly influence the membrane microstructure and, as a consequence, the membrane transport properties and thermal behavior (Fontananova et al. 2012).

Sulfonated PEEK-WC (SPEEK-WC), Fig. 1 Repetitive unit of the PEEK, PEEK-WC, and the SPEEK-WC (DS is the degree of sulfonation)

SPEEK-WC membranes have been also modified by thermal annealing and chemical cross-linking with a diamine in order to improve their long-term durability (Fontananova et al 2013). Various ex situ characterizations were carried out on the modified and pristine SPEEK-WC membranes, including ion exchange capacity, proton conductivity, liquid water uptake, counter-elastic index, chemical resistance in oxidative conditions, and gas permeability. The results indicated that the proposed methodologies are able to increase hydrolytic and oxidative stability of the SPEEK-WC membranes.

SPEEK-WC membranes offer a higher resistance to water and methanol vapor transport than commercial Nafion membranes (which until today are the most commonly used membranes for PEMFCs). Also, the H_2 and O_2 permeabilities of the SPEEK-WC membranes are lower in comparison with Nafion (Fontananova et al. 2010).

These results justify the conclusion that less crossover problems may occur in the PEMFCs

operating with SPEEK-WC membranes compared to PEMFCs operating with Nafion.

The lower permeability of the SPEEK-WC-based membranes was due to their lower diffusion coefficients, caused by the higher stiffness of the aromatic polymer chains of SPEEK-WC with respect to Nafion.

Functional additives were also heterogenized in SPEEK-WC membranes, in order to improve their properties for applications in PEMFCs.

Mixed matrix membranes were prepared dispersing amorphous zirconium phosphate sulfophenylenephosphonate ($Zr(HPO_4)(O_3PC_6H_4SO_3H)$), in the SPEEK-WC matrix (Regina et al. 2006). The membranes obtained were characterized by a homogeneous distribution of the inorganic filler. The membranes exhibited a significantly lower swelling degree in water and methanol compared to the polymeric membranes without the filler.

Heteropoly acids (HPAs) have been also dispersed into the membrane dope solutions to

prepare mixed matrix membranes (Fontananova et al. 2010, 2012). The embedding of the inorganic HPAs, in particular the silicotungstic acid ($\text{H}_4\text{SiW}_{12}\text{O}_{40} \cdot n \text{H}_2\text{O}$), in SPEEK-WC membranes, enhanced the proton conductivity because the HPAs, uniformly distributed on a nanometric scale, interconnected better the ionic cluster of the polymer providing a favored pathway for protons hopping.

Sulfonated PES (SPES)

Monica Pica
University of Perugia, Department of
Pharmaceutical Sciences, Perugia, Italy

Sulfonated poly (ether sulfone) (SPES) is a sulfonic acid functionalized poly (arylene) ionomer,

Sulfonated PES (SPES), Fig. 1 Repeat unit structure of SPES

in which the aromatic rings of the polymer backbone are connected through alternate sulfone ($-\text{SO}_2-$) and (ether $-\text{O}-$) linkages (Fig. 1).

The SPES precursor, PES, is a well-known engineering thermoplastic polymer, totally devoid of aliphatic hydrocarbon groups, with a glass transition temperature of 230 °C, widely used in ultrafiltration membranes, due to its high mechanical and chemical stability (Kim et al. 1999).

The sulfonation of poly(arylene ether sulfone)s was first investigated by Noshay and Robertson in 1976, who developed a mild sulfonation procedure for the commercially available bisphenol-A-based PES (Noshay and Robeson 1976).

SPES ionomers can be prepared by post-sulfonation of PES: the reaction is an aromatic electrophilic substitution and PES is notoriously difficult to sulfonate due to the electron withdrawing effect of the sulfone linkages, which deactivate the adjacent aromatic ring (Guan et al. 2005). The sulfonic group is generally attached to the activated position ortho of the aromatic ether. The sulfonation has been carried out in heterogeneous and homogeneous media, with different sulfonating agents and solvents: $\text{SO}_3/\text{CH}_2\text{Cl}_2$, $\text{ClSO}_3\text{H}/\text{CH}_2\text{Cl}_2$, SO_3 -triethylphosphate/ CH_2Cl_2 , and oleum/concentrated H_2SO_4 . The degree of sulfonation (DS) can be controlled by changing the time, temperature, and the sulfonating agent/PES ratio. No more than one sulfonic group per repeat unit is generally substituted. By modifying the backbone structure of PES, locally and densely sulfonated PES were prepared through a selective post-sulfonation reaction on the pendant side phenyl groups along the main chains (Matsumoto et al. 2009). The sulfonation process via the metalation, such as lithiation, allowed the

introduction of sulfonate groups also in the *ortho*-sulfone site of PES (Kerres et al. 1996).

Direct polymerization of sulfonated monomers allowed the preparation of SPES copolymers exhibiting higher degree of sulfonation with respect to those obtained by post-sulfonation reaction (Wang et al. 2002; Matsumoto et al. 2009).

SPES ionomers are soluble in widely used polar solvents, such as DMF, DMAc, NMP, and at high DS they are soluble in hot water. SPES membranes can be prepared by casting organic solutions. The microstructure of SPES membranes is that typical of sulfonic acid membranes: a microphase separation between hydrophobic and hydrophilic regions occurs in the presence of water. The hydrophilic regions are responsible for water adsorption and the hydrophobic regions made up by the polymer backbone provide dimensional and mechanical stability (Dai et al. 2007). The DS affects the two phase-separated microstructures and the water adsorption, which, in turn, influences proton conductivity and mechanical properties. In order to get the best compromise between high conductivity, limited water uptake, and good mechanical properties, several approaches are possible: cross-linking of high sulfonated ionomers, block copolymers, and composite membranes (Iojoiu et al. 2005). SPES membranes showed also a methanol permeability lower than that of perfluorosulfonic acid membranes, the proton conductivity being the same, so that they are promising for applications in direct methanol fuel cells (Dai et al. 2007).

Sulfonation Reaction

Monica Pica

University of Perugia, Department of
Pharmaceutical Sciences, Perugia, Italy

A sulfonation reaction consists in the attachment of the $-\text{SO}_3\text{H}$ group on an organic molecule through the formation of a covalent C-S or, less frequently, an N-S bond (Kucera and Jancar 1998). Sulfonation is well known and widely used in chemical industry for many applications, such as the production of surface-active agents, detergents, ion-exchange resins, etc. Among the commercial polymers which can be sulfonated are polystyrene (PS), polyether ketone (PEK), polyether ether ketone (PEEK), polysulfone (PSU), polyphenylsulfone (PPSU), and polyphenylene sulfide (PPS) (Iojoiu et al. 2005). Sulfonated ionomers are defined as macromolecular compounds containing the $-\text{SO}_3\text{H}$ ionogenic groups. The introduction of $-\text{SO}_3\text{H}$ groups in a polymer chain provides properties such as ion-exchange capacity, hydrophilicity, solubility in polar solvents, and proton conduction

(Fathime et al. 2007). Sulfonated polymers are employed for the fabrication of membranes for fuel cells and electrodialysis, exchange resins and catalysts, surgical instruments, implants, and wound healing dressings. The sulfonation reaction can occur on the monomer before polymerization (pre-sulfonation) or on the polymer (post-sulfonation). In the case of a post-sulfonation, the degree of sulfonation depends on the type of reagent, substrate, reaction time, and temperature. This leads to a statistical distribution of the sulfonic acid groups (Kucera and Jancar 1998). The pre-sulfonation of monomers allows a better control of the degree of sulfonation, and no chemical treatment after polymerization is necessary (Gil et al. 2004).

The sulfonation reaction of aromatic rings occurs more easily than that of aliphatic compounds: the sulfur atom of a sulfonating agent is bonded to more electronegative atoms such as oxygen and acts as electrophilic center reacting with the delocalized π electron system of the aromatic ring (Kucera and Jancar 1998). The reaction can be considered a bimolecular reaction (S_E2 mechanism):

- i. A π complex between an aromatic compound (ArX) and a sulfonating agent (e.g., SO_3) is first transformed in a σ complex (rate determining step).
- ii. The sulfonated aromatic derivative is then obtained by the quick release of an X^+ species from the σ complex.

The presence of various substituents on the aromatic ring can result in the insertion of the $-SO_3H$ group in preferential positions and the formation of specific ionomers: the sulfonation of aromatic compounds bearing substituents, such as $-NR_2$, $-NHR$, $-NH_2$, $-NHCOR$, $-OH$, $-OR$, $-SH$, $-SR$, -alkyl-, -halo-, and NO , results in the prevalent formation of *para*-isomers than *ortho*-isomers; differently, in the presence of substituents such as $-R_3N^+$, $-R_2S^+$, $-NO_2$, $-CN$, $-CHO$, $-COCl$, $-SO_2R$, $-SO_3H$, $-COOR$, and $-CONH_2$, the insertion of the $-SO_3H$ group mainly occurs in the meta-position (Kucera and Jancar 1998).

The main sulfonating agents can be classified into three groups (Kucera and Jancar 1998):

1. Electrophilic reacting agents (sulfuric acid, oleum, chlorosulfonic acid, free sulfur trioxide and its complexes, trimethylsilylchlorosulfonate, etc.)
2. Nucleophilic reacting agents (sulfites and hydrogensulfites, sulfur dioxide), which react with halogen derivatives and unsaturated compounds containing multiple bonds
3. Radical reacting agents ($SOCl_2$, SO_2+Cl_2 , SO_2+O_2)

Polymer sulfonation can be carried out as a heterogeneous or a homogeneous reaction in hydrocarbons or chlorinated solvents (Kucera and Jancar 1998). As an example, the heterogeneous sulfonation of PS is very interesting especially for industrial applications. Some examples reported:

- The (solid-gaseous) heterogeneous sulfonation of PS beads of 450 nm in diameter with gaseous SO_3 above fuming sulfuric acid, for 3 days at room temperature
- The (solid-liquid) sulfonation of PS powder with 100 % H_2SO_4 in the presence of Ag_2SO_4 , preventing the formation of side products, for 5–15 min

Sulfur Odorous Compounds Removal by Pervaporation

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Sulfur oxide emissions generated by vehicle engines may cause some serious problems, for instance, inducing the formation of acid rain, decreasing the efficiency of catalytic converters, and promoting corrosion of engine parts. As a result, removal of sulfur from gasoline has received increasing attention with growing environmental awareness. Much attention has been paid to pervaporation (PV) which is a promising and feasible technology for desulfurization of gasoline since Grace Davison Company offered the PV membrane-based S-Brane process in 2002. Mercaptans, sulfides, disulfides, thiophene, and its derivatives are the typical sulfur components of fluid catalytic cracking (FCC) gasoline in which thiophenic sulfur represented a large fraction (80 % and over) after alkali cleaning process (Lin et al. 2009). For this reason, the main aim for FCC gasoline desulphurization is to remove thiophenic sulfur compounds, at present. Unwisely, it is more difficult to remove thiophenic sulfur impurities than to other sulfur compounds in FCC gasoline.

Quite a lot of PV membranes for sulfur removal have been reported by Grace Davison Company (White et al. 2004). PUU membrane showed higher sulfur enrichment than polyimide (PI) and other commercial membranes they reported. However, its practical application is not satisfying due to the low flux (less than 0.1 kg/(m².h)). Exxon Mobil Research and Engineering Company presented two types of membrane for desulphurization which are nonionic and ionic membranes. Reported nonionic membranes included polyvinylpyrrolidone (PVP) and cellulose triacetate (CTA), while the preferred ionic membranes (Saxton et al. 2004) included Nafion RTM-type acidic membranes, e.g., Nafion

RTM117, that had been optionally treated by ion-exchange reaction or with bases. The good news is that certain investigations have been made on some commercial membranes. Marathon Oil Company also studied the process for removing sulfur from hydrocarbon, while Trans Ionics Corporation has developed a PV process, TranSep-S, for sulfur removal from gasoline boiling range feeds.

Besides, some polymer materials with sound sulfur removal performance, for instance, cross-linked polyethylene glycol/polyethersulfone (PEG/PES) composite membranes, were also used for FCC gasoline desulphurization (Lin et al. 2006). The performance of polydimethylsiloxane (PDMS) and polyimide PI membrane composite membranes was studied for sulfur removal from model gasoline (Qi et al. 2006). It has been showed that the membrane modification methods lead to achieve high selectivity or high flux (Lin et al. 2009). For example, cross-linking modification for PEG increased sulfur enrichment factor from 3.31 to 7.31 for model compounds feed and from 1 to 3.05 for FCC gasoline. AgY zeolite incorporation in PDMS membranes led to a significant increase in total flux. At the same time, higher sulfur enrichment factor and permeation flux were obtained from PEG/polyurethane (PU) blend membranes for gasoline desulphurization. It should not be ignored that the performance for various membranes mainly depends on the properties of the membrane materials while the types of membrane structure also have a significant influence on the membrane performance. Ceramic-supported PDMS membrane exhibits a higher permeation flux and an acceptable sulfur enrichment factor in comparison with those composite membranes using polymeric supports (Xu et al. 2010). The operating parameters of PV, including feed temperature, feed concentration, feed flow rate, permeate pressure, etc., have significant impacts on membrane performance. Take ceramic-supported PDMS membrane as an example; the increase of sulfur content in feed leads to a higher total flux but a lower sulfur enrichment factor. By increasing the feed temperature, the total flux increased while sulfur enrichment factor decreased. It was

appropriate that low permeate pressure and high feed flow rate were beneficial to improve total flux and sulfur enrichment factor (Xu et al. 2010).

Supercritical CO₂ Hybrid Membrane Systems

Gilbert M. Rios
Place Eugene Bataillon, IEM – European
Membrane Institute, Montpellier, France

Supercritical carbon dioxide is a fluid state where CO₂ is held at or above its critical temperature (31.10 °C or 304.25 K) and critical pressure (72.9 atm or 7.39 MPa). Carbon dioxide usually behaves as a gas in air at standard temperature and pressure or as a solid called dry ice when frozen. If the temperature and pressure are both increased to be at or above the critical point for carbon dioxide, it can adopt tunable properties midway between a gas and a liquid: notably a very low viscosity (as for gas) and at the same time a very high density (as for liquids). CO₂ offers also a low toxicity and environmental impact, while the relatively low process temperature and its stability

protect most treated species from damage or denaturing. Thus, supercritical CO₂ has become an important commercial and industrial solvent particularly for chemical extraction (for decaffeinating as an example), for dry cleaning (much more attractive than hydrocarbons or perchloroethylene), for separation (by simple pressure release and control of solubility, it is possible to separate different fractions), or to produce micro- and nanoscale particles.

The use of SCCO₂ with porous barriers (MF, UF, NF) can lead to the development of new original or intensified hybrid processes. Basic ideas are summarized on the Fig. 1 above.

The part of the diagram which corresponds to high mass fraction of solvent (green on the left) may be associated to new continuous and compact processes of extraction/separation. In a first vessel, SCCO₂ extraction is carried out from mixed solutions; then the SC solution obtained is passed through a nanofiltration membrane where high-molecular compounds (retentate) are separated from small-molecular species (permeate). By a controlled pressure drop on the permeate side, solubility can be lowered, thus inducing the separation of small-molecular species (solid state) from pure carbon dioxide (gaseous); the stream of CO₂ may be recycled to the extraction chamber. On the other side, heavy molecules may be separated from the retentate by a controlled temperature change (solubility modification), before recycling the stream of SCCO₂ at constant pressure. Among the main advantages of the process are the following: important permeate flows may be obtained because of the low viscosity of SCCO₂ (10 times higher than for water); as compared to classical SC extraction process, a lot of energy may be saved because pressure cycles (relaxation/compression from standard to SC conditions) only apply to the small fraction of carbon dioxide corresponding to permeate; only one compression unit is necessary for extraction and separation steps. The feasibility of the concept has been demonstrated on different model and real solutions.

By working in the part of the diagram which corresponds to low mass fraction of solvent (purple on the right), an original process to enhance the fluidity of thick liquids in order to

Supercritical CO₂ Hybrid Membrane Systems, Fig. 1 Supercritical CO₂ hybrid membrane systems

facilitate their filtration in a membrane unit has been developed. Indeed, by inflating as an example sticky oils with the injection of pressurized CO₂, one can obtain a pseudo-homogeneous solution which exhibits a viscosity down to 10-time lower. Membrane filtration is much easier, and a pure liquid may be recovered after the operation on the permeate side by dropping pressure. Undoubtedly, this new process allows getting a better product quality than other ones already tested: at high temperatures or with chemical additives. In particular this new original process can be a one-stop tool for the treatment of fragile biological products. It represents a sustainable and safeguarding environment technology that does not ask for posttreatments (for energy or chemical additives).

Superhydrophobicity

Wolfgang M. Sigmund and Shu-Hau Hsu
 Department of Materials Science and Engineering, University of Florida, Gainesville, FL, USA

Department of Energy Engineering, Hanyang University, Seoul, Republic of Korea

References

Paolucci-Jeanjean D, Rios GM, Sarrade S (2009) Membrane technologies and supercritical fluids – recent advances. In: Pabby AK, Rizvi SSH, Sastre AM (eds)

Superhydrophobicity is a surface phenomenon that indicates a very low affinity to water, and, in turn, the surface is very difficult to be wetted. A generally accepted definition of superhydrophobicity is to have a water contact angle above

Superhydrophobicity, Fig. 1 Water droplet forms a bead on superhydrophobic surface (Image by Hsu SH and Sigmund W, University of Florida)

150° and a start-rolling angle lower than 10° at room temperature and ambient pressure. Therefore, water droplets on superhydrophobic surfaces typically form spherical beads (Fig. 1), and can be easily shaken away from the surface. For explanation on contact angle, please refer to the section of Young's Model. This extreme water repellency widely exists in a variety of natural species. Some crucial functions for these species are provided through this property, such as the reduction of surface contamination and the ability of performing underwater respiration or sustaining the impact from raindrops. More details can be found in the section of lotus effect and hairy superhydrophobic surface.

Superhydrophobic surfaces with the highest contact angles are the combination of surface chemistry and topography. The surface energy has to be low enough to reduce the adhesion between water and solid, and furthermore it has to be rough enough to lower the solid area which is in contact with water. Multiple scales of roughness, namely, hierarchical structures, with additional nanosized roughness existing on the top of a micron-sized feature, are often needed to achieve superhydrophobicity. More details can be found in the section of the Cassie-Baxter Model.

Since 2000, interest in superhydrophobicity has not only increased concerning the science behind this unique phenomenon but also concerning the design and engineering of such

superb anti-wetting surfaces. The most prominent effect of superhydrophobicity is the self-cleaning ability, where dirt can be effortlessly picked up and removed while water droplets roll off the surface. The consumption of water and energy is minimized to keep the surface smudge free. Other potential applications are also related to the field of energy conservation or environmentally friendly technologies, such as anti-biofouling, anticorrosion, drag reduction, and deicing surface.

Superparamagnetic Properties of Membranes

Zbigniew J. Grzywna and Aleksandra Rybak
Department of Physical Chemistry and
Technology of Polymers, Silesian University of
Technology (SUT), Gliwice, Poland

Magnetic separations have for decades been essential processes in diverse industries ranging from steel production to coal desulphurization. In such settings, the magnetic fields are used in continuous flow processes as filters to enrich or remove magnetic impurities (Yavuz et al. 2009).

The interest in magneto-responsive colloidal systems and magnetic particles is steadily increasing. Both nano- and micron-sized magnetic particles have been used successfully for a wide range of applications, including treatment, diagnosis, chemical, environmental and biological separation processes. The suspensions of micron-sized magnetic particles are called magneto-rheological fluids and are preferable for some applications where the separation of magnetic microparticles from a liquid medium can be executed easily and

Superparamagnetic Properties of Membranes,

Fig. 1 Dependence of (a) a powder coercivity on the particle size and (b) a magnetization (M) on an external

magnetic field (H) for magnetic particles with various particle sizes (hysteresis loops)

economically compared with that of magnetic nanoparticles (Xu et al. 2008). Promising strategy for improving the separation properties of polymeric films is the incorporation of magnetic particles into the polymer matrix. In many cases, the polymer matrix functions as a dispersion medium which stabilizes and protects the added particles (Goyal et al. 2011). While these filler particles, incorporated in the polymer matrix, enhance membrane's mechanical, optical, magnetic or electrical properties (Zhang et al. 2006). Such procedures produce novel functionalized inorganic-organic composites, which have found extensive applications, like, for instance, in the gas separation (air) (Rybak et al. 2009a, b, 2012, 2013, 2014a, b; Grzywna et al. 2010; Krasowska et al. 2012; Borys et al. 2013; Dudek et al. 2013; Strzelewicz et al. 2013), pervaporation (Rybak et al. 2013), bioapplication, water treatment processes (Wandera et al. 2010; Yang et al. 2013; Dudek et al. 2012).

Superparamagnetic single domain nanoparticles dispersed in the liquids are called magnetic fluids, or ferrofluids. They can easily be magnetized in an external magnetic field and immediately redispersed once the magnet is removed (Tural et al. 2009). The most popular nanoparticles are iron oxide particles in two main forms, magnetite (Fe_3O_4) and its oxidized form maghemite ($\gamma\text{-Fe}_2\text{O}_3$). They have attracted extensive interest due to their superparamagnetic properties and their potential applications in many

fields, like: terabit magnetic storage devices, catalysis, sensors, and high-sensitivity biomolecular magnetic resonance imaging (MRI) for medical diagnosis and therapeutics (Papaefthymiou 2009).

Many researchers have carried out work on the application of these nanoparticles in preparation of the magnetic membranes. They have been applied in controlled release of chemicals, microreactors, biomedical, or chemical sensors, in the separation of paramagnetic and diamagnetic gaseous species at room temperature (He , N_2 , O_2 , Ar , and air separation), protein isolation, cell separation, drug delivery, biocatalysis, ion selectivity experiments, food processing, and wastewater treatment (Wandera et al. 2010; Yang et al. 2013; Dudek et al. 2012). The effectiveness of these membranes' activity depends mainly on interaction between these two materials (polymer matrix and filler), their compatibility, and good dispersion of inorganic phase. Numerous chemical modifications of polymer and inorganic phases and application of appropriate preparation techniques could be used to improve these features.

This type of membrane has the special properties because of the superparamagnetic behavior of added fillers. These particles have to be single magnetic domains with no hysteresis loops. This would be possible when their diameter will be between 2 and 50 nm (the size of nanoparticles is below a critical value D_c), depending on the used material (Fig. 1a). Another property is that

membrane's magnetization can randomly flip direction under the influence of temperature, and this typical time between two flips is called the Néel relaxation time τ_N and is given by the following Néel-Arrhenius equation:

$$\tau_N = \tau_0 \exp\left(\frac{KV}{k_B T}\right) \quad (1)$$

where:

τ_N – the average time for the nanoparticle's random flip of magnetization due to the thermal fluctuations,
 τ_0 – the time, characteristic for the material, called the attempt time,
 K – the nanoparticle's magnetic anisotropy energy density,
 V – volume,
 k_B – the Boltzmann constant,
 T – the temperature.

They will be in the superparamagnetic state in the absence of external magnetic field, when the time used to measure the magnetization of the nanoparticles is much longer than the Néel relaxation time, and their magnetization appears to be in average zero. In this state, an external magnetic field is able to magnetize the nanoparticles, just like in the case of a paramagnet. However, their magnetic susceptibility is much larger. They have a large constant magnetic moment and behave like a giant paramagnetic atom with a fast response to applied magnetic fields (Fig. 1b) with negligible remanence (residual magnetism) and coercivity (the field required to bring the magnetization to zero).

The magnetic moments of superparamagnetic nanoparticles in an external magnetic field tend to align along the applied field, leading to a net magnetization. The magnetization curve is a reversible S-shaped increasing function. This function is quite complicated but in some cases this function may take the following forms:

- If all the particles are identical, their easy axes are all oriented parallel to the applied field and the temperature is low enough

($T_B < T \lesssim KV/(10 k_B)$), then the magnetization is given as:

$$M(H) = n\mu \tanh\left(\frac{\mu\mu_0 H}{k_B T}\right) \quad (2)$$

- If all the particles are identical and the temperature is high enough ($T \gtrsim KV/k_B$), then the magnetization is given as:

$$M(H) = n\mu L\left(\frac{\mu\mu_0 H}{k_B T}\right) \quad (3)$$

Where:

n – the density of nanoparticles in the sample,
 μ_0 – the magnetic permeability of vacuum,
 μ – is the magnetic moment of a nanoparticle,

and $L(x) = \frac{1}{\tanh(x)} - \frac{1}{x}$ is the Langevin function.

It can be seen from these equations that large nanoparticles have a larger μ and so a larger susceptibility. This explains why superparamagnetic nanoparticles have a much larger susceptibility than standard paramagnets: they behave exactly as a paramagnet with a huge magnetic moment.

Magnetic nanoparticle fillers exhibit a variety of unique magnetic phenomena that are drastically different from those of their bulk counterparts. The magnetic properties of these membranes are influenced by nanoparticles morphology, structure, size, and its distribution.

That's why the appropriate magnetic nanoparticle preparation method, which has a large effect on shape, size distribution, and surface chemistry of the particles should be selected. Such method also determines to a great extent the distribution and type of structural defects or impurities in the particles. All these factors affect magnetic behavior. The most employed method is coprecipitation in which the size and shape of the nanoparticles can be controlled by adjusting pH, ionic strength, temperature, nature of used salts, or the concentration.

The next method applies a microemulsion which is a stable isotropic dispersion of two immiscible liquids and surfactant. This dispersion consists of nanosized domains of one liquid in the other phase, stabilized by the surface-active

molecules at the phase boundary. The size of the spherical nanoparticles can be tailored and tuned by changing the size of the water pool. The third method is the decomposition of iron precursors in the presence of hot organic surfactants. It results in samples with good size control, narrow size distribution, appropriate crystallinity, and the well-dispersed nanoparticles (Cullity and Graham 2009; Dave and Gao 2009).

The development of the high-quality nanocrystals, with greater surface areas and more responsive magnetic cores, will allow an expansion of the magnetic membranes in many areas of industry, medicine, and various separation techniques.

Supported Liquid Membrane

Vladimir S. Kislik

Campus Givat Ram, Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

Supported or immobilized liquid membrane (SLM or ILM) is one of the three-phase liquid

Supported Liquid Membrane,**Fig. 1** Scheme of a supported liquid membrane

membrane systems in which the membrane phase (liquid) is held by capillary forces in the pores of microporous polymeric or inorganic film. Support separates two aqueous solutions: the feed (donor) and the strip (receiving, acceptor) phase (see Fig. 1). The compounds of interest are separated from the aqueous sample feed phase into an organic liquid membrane phase, and then they are continuously back extracted to the other side of the membrane into the strip phase. The driving force is the difference in concentration of the compounds between the phases.

A SLM usually consists of an organic solvent immobilized in the pores of a hydrophobic microfiltration membrane. In many cases, the organic solvent contains a carrier which is able to selectively bind one of the components from the separated mixture (feed solution) which improves selectivity. The general term for mass transport through liquid membranes under the chemical potential gradient as a driving force is permeation. The permeants from liquid feed (donor solution) are transported through a nonporous, polymeric, or liquid membrane phase and desorbed into

another liquid phase. Some authors called this process pertraction. While solvent extraction is an equilibrium process, SLM separation is a dynamic, nonequilibrium diffusion process governed by the kinetics of the membrane transport. Therefore, the amount of transported compounds is not proportional to the amount of the organic, membrane phase as it is in extraction.

Usually SLMs are based on hydrophobic organic solvent immobilized in a polymeric membrane separating two aqueous solutions. In some cases, the arrangements are opposite, and the pores in the support separating two nonaqueous phases are impregnated by water. The SLM may be fabricated in different geometries. Flat sheet SLM is useful for research, but the surface area to volume ratio is too low for industrial applications. Spiral-wound and hollow-fiber SLMs have much higher surface areas of the LM modules (103 and $104 \text{ m}^2/\text{m}^3$, respectively).

The main problem of SLM technology is the stability: the chemical stability of the carrier, the mechanical stability of porous support, etc. Relatively new LM technologies, developed

with the aim to improve stability parameters, are gel LM formed by liquid-phase gelation in the pores, ion-exchange membranes as supports, ionic liquids (ILs) used as a membrane phase, swollen polymeric membranes, and polymeric inclusion membranes (PIM), formed by casting the solution of polymer and plasticizer (solvent characterized by high viscosity) to form a thin, flexible, and stable film. All these technologies are considered as modifications of the SLMs. SLM can also be formed by immobilizing the membrane phase between two nonporous films which are permeable to transported substances and usually nonselective. The latter is much more stable but is less suitable due to a higher mass transfer resistance.

Successful applications of SLMs are possible due to their advantages compared to other separation methods. The main advantages of SLMs are the small amounts of organic phase and extractant (carrier) used, one-step mass transfer, the possibility of achieving high separation factors, concentration of extracted compound(s) during separation, and low separation costs. SLMs have been used to solve an increasing number of separation problems, including metal and organic compound separation and the resolution of stereoisomers. The unique flexibility and ease of preparation of SLMs in various configurations, despite some stability and lifetime problems, have resulted in their application in many sometimes very different fields where selective and efficient separation methods are necessary: in hydrometallurgy, biotechnology, wastewater treatment, the capture of greenhouse gases, analytical and environmental chemistry, and in the pharmaceutical industry.

SLM separation systems can be classified into several different groups, according to their preparation methods, types of membrane support and membrane liquids, module types used, and their application (for details, see Dzygiel and Wieczorek 2010).

Supported Liquid Membrane for Enantioselective Separation

Keiji Sakaki

National Institute of Advanced Industrial Science and Technology (AIST), Research Institute for Sustainable Chemistry, Tsukuba, Ibaraki, Japan

An enantiomer is one of two stereoisomers that are mirror images of each other and nonsuperposable. This feature of an enantiomer is called “chirality.” Many chiral molecules not only appear in nature but also can be synthesized artificially. Amino acids and sugars are the representative chiral molecules found in nature, and they exist in the form of one isomer. Enantiomeric pairs frequently show different biological activity from each other. So the technology to separate enantiomers has been an important subject in the industries dealing with pharmaceuticals, foods, agrochemicals, and so on. However, enantioselective separation has been a challenging subject because each enantiomer has the same physical and chemical properties.

Some methods have been reported for enantiomeric separation, for example, preferential crystallization, chromatographic separation, enzyme-mediated resolution, and membrane-based separation (Xie et al. 2008). Among them, membrane-based method has some advantages over the other methods, such as low energy demand, continuous operation, and easy scale-up. Both liquid membrane and solid membrane have been applied to enantiomeric separation. The important factor of membrane-based enantioselective separation is the way how to give the function of chirality recognition to membranes. In the process using solid membranes, chirality recognition exists in main polymer chain, chiral polymer branch, and doped chiral selector or cavity formed by

Supported Liquid Membrane for Enantioselective Separation, Fig. 1 Concept of transportation in SLM

Supported Liquid Membrane for Enantioselective Separation, Fig. 2 An example of chiral crown ether

molecular imprinting (Higuchi et al. 2010). On the other hand, in the separation with liquid membranes, enantioselective carriers are usually doped in the liquid membranes. In a supported liquid membrane (SLM), a liquid containing enantioselective carriers is impregnated into a porous support membrane. The separation concept in SLM process is shown in Fig. 1. On the membrane surface in the feed phase, a doped carrier combines with one isomer more preferentially than the other, and the carrier-isomer complex diffuses in the liquid membrane toward the strip phase. On the membrane surface of strip phase, the carrier releases the isomer. In the SLM process, the driving force is the concentration gradient of co- or counterions (indicated as X in Fig. 1) between feed and strip phases. Typical carriers used in SLM processes are crown ethers. Figure 2 shows the structure of one of crown

Supported Liquid Membrane for Enantioselective Separation, Fig. 3 β -Cyclodextrin

ethers that shows high enantioselectivity toward amino acids (Shinbo et al. 1993). Cyclodextrins are used as chiral carriers in aqueous SLM (Armstrong and Jin 1987). The molecular structure of β -cyclodextrin is shown in Fig. 3. The improvement of membrane stability is the key factor for the industrial application of SLM process (Kocherginsky et al. 2007).

Supported Magnetic Ionic Liquid Membranes

Angel Irabien

Departamento de Ingeniería Química y Química Inorgánica, Universidad de Cantabria, Santander, Spain

Supported ionic liquid membranes (SILMs) have been studied after immobilizing selected ionic liquids in polymeric or ceramic supports (Bara et al. 2009; Luis et al. 2009; Scovazzo et al. 2009). The influence of pore size and the stability evaluation regarding its hydrophobic or hydrophilic nature has been reported in the literature (Cserjesi et al. 2010; Neves et al. 2010).

Although SILMs present advantages due to the room temperature ionic liquid (RTIL) properties, their applications are still limited mainly associated to problems in their stability and/or long-term behavior (Criscuoli and Drioli 2008; Scovazzo 2009).

The magnetic behavior of a new generation of RTILs containing metal ions is recently under study in the literature. The combination of general RTIL features (e.g., chemical and thermal stability nonvolatile character and non-flammability) with new properties due to the incorporation of a metal ion has opened a new research area which is starting to attract a wide interest.

The MILs 1-butyl-3-methylimidazolium tetrachloroferrate ([bmim][FeCl₄]) and 1-butyronitrile-3-methylimidazolium tetrachloroferrate ([n-bmim][FeCl₄]) were the first reported MILs to respond to an external magnet of about 0.55 T due to changes of its organization structure. MILs based on different transition metal ions such as iron, cobalt, manganese, and gadolinium showing a very interesting magnetic response with potential applications for magnetic and electrochromic switching have been reported, and the possibility of magnetic transport of a gas in MILs has been demonstrated, illustrated by the change in N₂ bubbles trajectory in the presence of a magnetic field (Hayashi and Hamaguchi 2004; Hayashi et al. 2006; DelSesto et al. 2008).

The application of an external magnetic field may modify the physicochemical properties, such as solubility or surface tension, by tuning the magnetic conditions. The dependence between the magnetic field intensity and the binary MIL/water equilibrium has been also observed, showing the increase of solubility of MILs in aqueous medium [16], which could improve the process efficiency. Other recent applications have shown a benzene solubility increase in the paramagnetic MIL [bmim][FeCl₄] when applying a rotational magnetic field or the improvement of phenolic compounds extraction in the MIL [3C₆PCl₄][FeCl₄] in the presence of a magnet (Deng et al. 2011).

The SMILMs were prepared using commercial microporous membranes from Millipore Corporation (USA). These supports are hydrophobic polyvinylidene fluoride (PVDF) membranes with a pore diameter of 0.22 μ m and an average thickness of 125 μ m. The immobilization procedure has been previously described [19]. To immobilize the MILs, the polymeric microporous membrane was introduced into a vacuum chamber for 1 h in order to facilitate the wetting. Afterward, drops of MILs were spread out at the membrane surface using a syringe keeping the vacuum inside the chamber, and, finally, the liquid excess on the membrane surface was wiped up softly with a tissue. The increase of weight and thickness was measured before and after the immobilization procedure (Albo et al. 2012; Ferguson and Scovazzo 2007; Condemarin and Scovazzo 2009).

The CO₂ permeability ratio (P(B)/P(0)) at different magnetic field intensities (B) (Fig. 1) shows the influence of an external magnetic field in the gas permeabilities of SMILMs. A recently published paper [20] has been able to show the influence of the external magnetic field application on gas permeability (CO₂, N₂, and air) through SMILMs in the range of 0–1.5 T. The gas permeability variation is related to the MIL viscosity change. Experimental results show that gas permeability increases as a function of the applied magnetic field depending on the magnetic ionic liquid (Santos et al. 2013).

Surface Analysis

Teresa Poerio

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The surface analysis is the study of the membrane surface properties by means of surface analysis

Surface Analysis, Table 1 Main surface analysis techniques

Surface analysis techniques	Information
Attenuated total reflection Fourier transform infrared (ATR-FTIR)	The presence of membrane surface functionalities such as carbonyl, hydroxyl group, etc.
X-ray photoemission spectroscopy (XPS)	Chemical composition, variations in surface composition (Briggs 1998)
Static secondary ion mass spectrometry (SSIMS)	Chemical composition, variations in surface composition (Briggs 1998)
Energy dispersive x-ray spectroscopy (EDX)	Chemical composition, variations in surface composition
Optical microscopy (OM)	Topography, magnified images
Laser confocal scanning microscopy (LCSM)	Topography, images with increased optical resolution and contrast
Scanning electron microscopy (SEM)	Morphology, topography
Environmental scanning electron microscopy (ESEM)	Morphology, topography, micrographs of wet and/or uncoated samples
Contact angle measurement (CAM)	Surface energy, wettability
Atomic force microscopy (AFM)	Forces of the order of a few piconewtons surface roughness
Electrophoretic light scattering (ELS)	Surface zeta potential

techniques; they provide information on the morphology, topography, chemical composition, and wettability (Adamsons 2000; Bubert and Jenett 2002; Xu et al. 2009). The main used techniques and the information they give are listed in the following Table 1:

Synonyms

Membrane charge; Surface charge

The **surface charge density** of a membrane is the total electric charge per unit of membrane surface area.

When a membrane surface is put in contact with a fluid containing charged species, several chemical interactions take place such as acid/base dissociation, ionization of functional groups, adsorption of ions on the membrane surface, and/or the partial dissolution of the membrane material (Cavaco Morão et al. 2006). Chemical equilibrium and the stabilizing effect of the solvent generally lead to the interface acquiring a net fixed electrical charge (most often negative) (Albrecht et al. 2013). The surface charge causes electrostatic attraction of counterions and the repulsion of co-ions, while the random thermal motion causes diffusion of the ions in the solution. These coupled phenomena create an electric double layer (EDL) with a net charge in the region near the membrane surface (Probstein 2005).

According to the Stern model (Stern 1924), the surface charge is distributed in three layers: (a) the

Surface Charge Density,

Fig. 1 Schematic of the electric double-layer structure, caused by a membrane surface charge density, illustrating the dependence of electric potential (ϕ) with distance from the surface (y)

intrinsic membrane charge on the membrane surface (σ_0); (b) the charge in the Stern layer (σ_s), related to counterions tightly bound to the surface; and (c) the charge of the diffuse layer (σ_d), which is required for overall electroneutrality:

$$\sigma_0 + \sigma_s + \sigma_d = 0 \quad (1)$$

The electric potential within the diffuse layer follows a Boltzmann distribution (Probstein 2005), as depicted in Fig. 1. The zeta potential (ζ), which is the potential at the boundary between the Stern layer and the diffuse layer, can be estimated through microelectrophoresis, electroosmosis, or streaming potential measurements (Bowen and Clark 1984). It is possible to calculate the diffuse layer charge density from zeta potential measurements by making use of the Gouy-Chapman equation (Cavaco Morão et al. 2006):

$$\sigma_d = \sqrt{2\varepsilon RT \sum_i C_i \left[\exp\left(-\frac{z_i F \zeta}{RT}\right) - 1 \right]} \quad (2)$$

where z_i and C_i are the valence and concentration of ionic species i , ε is the permittivity of the fluid, F is the Faraday constant, R is the universal gas constant, and T is the temperature.

The charge density in the Stern layer depends on the bulk solute concentration. Under

homogeneous adsorption, it can be described by a Langmuir isotherm (Molina et al. 1999):

$$\sigma_d = \frac{z_- e N X_- \exp\left(\frac{z_+ F \zeta - \Delta G_q}{RT}\right)}{1 + X_- \exp\left(\frac{z_+ F \zeta - \Delta G_q}{RT}\right)} \quad (3)$$

where z_- and z_+ are the valences of the anion and cation, respectively, e is the elementary charge, N is the total number of adsorption sites, X_- is the bulk anion molar fraction, and ΔG_q is the Gibbs free energy of chemical adsorption. Under heterogeneous adsorption, a Freundlich isotherm can be used to relate the charge density in the Stern layer to bulk concentration:

$$\sigma_d = a X_-^b \quad (4)$$

The surface charge density is a fundamental property of the membrane. It has a significant effect on its hydrophilicity, separation properties (Watanabe 1974), and fouling tendency (Breslau et al. 1980). Surface charge density and zeta potential vary with pH (Kim et al. 1996) and are dependent on the surface geometry (modifiable through casting), as there is a larger volume per unit surface area for a convex than a concave surface (Andelman 1995). Surface charge

density characterization is also useful in confirming surface modifications, such as in the development of highly selective membranes (Datta et al. 2010).

Graft polymerization

Surface modifications have been widely used in the material- and polymer-based industries over past three decades [17]. It has the advantage of imparting the desired properties to the surface of interest while keeping the properties of bulk intact. Different innovative physical and chemical surface modification techniques have been introduced by various researchers in the field of polymers [17]. Over many years, graft polymerization (Fig. 1) has been studied in various fields of industrial applications, using different innovative techniques including different kinds of chemical and physical approaches. Modification via graft polymerization has many advantages over other methods, such as its ease of use and controllable introduction of graft chains to the surface with the bulk properties unchanged. Grafting of side chains can be performed in two ways, grafting-from and grafting-to methods [17]. In the former

Surface Modification: Chemical Treatment, Fig. 1 Schematic diagram of the graft polymerization process

method, the membrane surface consists of reactive radicals, while in the latter case, grafting chains carry the reactive radicals to initiate grafting. The procedures involved in grafting to surfaces are not straightforward enough for industrial applications, although the precise control of chain structure is in principle easier than with other methods [17]. Grafting can be achieved using different chemical techniques such as chemical oxidation, plasma discharge method and UV irradiation, and physical methods, such as radiation polymerization [17].

Belfer (Belfer et al. 2001) modified TFC membranes by redox polymerization using both sulfopropyl methacrylate (SPM), which gave a negative charge, and polyethylene glycol ester of methacrylic acid (PEGMA), which gave a neutral charge. Results of this test revealed that the modified membranes had an improved resistance to fouling, while salt rejection was similar when compared to the unmodified membrane. In addition, the foulant layer was easily rinsed clean, indicating that reversible fouling was prevalent for the modified membrane, whereas for the unmodified membrane, the foulant layer could not be removed. In a subsequent study, Gilron (Gilron et al. 2001) investigated the effect of graft polymerization of PEGMA, SPM, and 2-acrylamido-2-methyl propane sulfonate (AMPS) onto a variety of TFC polyamide membranes. The results showed that the permeability was reduced by no more than 25 % and salt rejection increased as much as 3 %. The modified membrane with the highest permeability was grafted with AMPS, and the modified membrane with the highest salt rejection was grafted with PEGMA. In addition, for modified membranes, the level of fouling by organic constituents was reduced, and the effectiveness of cleaning the modified membranes was greatly improved.

In order to reduce surface roughness and create a more hydrophilic membrane, Freger [56] investigated how graft polymerization of acrylic acid (AA) altered the surface structure of modified polyamide TFC NF membranes. The results of their analyses indicated that a thin layer of hydrophilic polymer may be deposited on the surface of the membrane. AFM analysis revealed that

polymer grafting reduced membrane surface roughness by a negligible amount, which indicated little improvement to fouling resistance occurred. In addition, the grafted polymer was shown to fill the pores of the porous support and led to reduced permeate production, which was a highly undesired result of membrane modification.

Graft polymerization of hydrophilic polymers has been extensively studied and is able to provide promising results. However, some drawbacks to this procedure can be substantial. Pore size reduction is a major consideration since it is directly capable of greatly reducing membrane productivity.

Surface Modification: Introduction of Carboxyl Group

Isabel C. Escobar

University of Kentucky, Lexington, KY, USA

In order to maintain membrane processes as economical alternatives to conventional water treatment technologies, they must produce a high-quality permeate at a high rate and be able to maintain that production for an extended period of time. However, the relationship between flux and selectivity along with fouling introduces a challenge that must be addressed for all membrane applications. There are three main areas of interest when it comes to improving membrane performance: (1) the synthesis process, (2) the

Surface Modification: Introduction of Carboxyl Group, Scheme 1 PBI activation with chloromethyl benzoic acid

application process, and (3) the post-synthesis modification. Synthesis process improvement involves the techniques, methods, and materials of the manufacturing processes to produce a high-performance membrane. The application process involves the specific operating parameters for a membrane system. These include selecting the raw water characteristics, operating pressure, and cleaning intervals to allow the system to operate at maximum efficiency. Post-synthesis modification involves modifying the membrane after the initial manufacturing process is complete.

There are several objectives for post-synthesis modification, or surface functionalization, which include, but are not limited to: enhance selectivity with focus on rejection of monovalent ions, increase flux of water, and enhance fouling resistance. Key targets for surface-modified groups include decreasing the hydrophobicity of the membrane, reducing the surface roughness, and altering the surface charge of the membrane. Many membranes are naturally hydrophobic due to the polymers that are used in the manufacturing process (including the PBI used for the NF membranes in this project). A drawback of a membrane exhibiting a hydrophobic nature is that it increases

the required transmembrane pressure (TMP) that must be utilized for operation, since the solvent (i.e., water) is repelled by the surface of the membrane. However, if a membrane can be rendered hydrophilic, the water is attracted to and transported through the membrane at a much faster rate, which reduces the required TMP for operation. In addition, many solutes found in feed waters are hydrophobic, so utilizing a hydrophilic membrane could increase the membrane's selectivity and fouling resistance. The severity of abiotic fouling is also directly linked to the membrane's surface roughness. Membranes with higher surface roughness have distinct peaks and valleys and are more susceptible to fouling, and with a reduction of roughness, foulants are less likely to adhere to the membrane. Functionalization with oligomers may reduce surface roughness and further improved fouling resistance.

Surfaces, such as polybenzimidazole (PBI), can be activated using a highly reactive chloride group, which reacted with the amide group of the PBI backbone to add carboxyl groups to the surface (Schemes 1 and 2). The carboxyl groups serve three purposes: (i) provide negative charge on surface since it can either protonate or

Surface Modification: Introduction of Carboxyl Group, Scheme 2 Modification using EDC chemistry

deprotonate based on the solution pH, (ii) provide hydrophilicity to surfaces, and (ii) act as a platform for subsequent functionalization.

Free radical polymerization

Surface modifications have been widely used in the material- and polymer-based industries over

the past three decades (Kato et al. 2003). It has the advantage of imparting the desired properties to the surface of interest while keeping the properties of bulk intact. Different innovative physical and chemical surface modification techniques have been introduced by various researchers in the field of polymers (Kato et al. 2003). Over many years, graft polymerization has been studied in various fields of industrial applications, using different innovative techniques including different kinds of chemical and physical approaches. Modification via graft polymerization has many advantages over other methods, such as its ease of use and controllable introduction of graft chains to the surface with the bulk properties unchanged. Grafting of side chains can be performed in two ways, grafting-from and grafting-to methods (Kato et al. 2003). In the former method, the membrane surface consists

Surface Modification: Wet Chemical Oxidation, Fig. 1 Orbital interaction chart for a carbon radical and a carbocation

of reactive radicals, while in the latter case, grafting chains carry the reactive radicals to initiate grafting. The procedures involved in grafting to surfaces are not straightforward enough for industrial applications, although the precise control of chain structure is in principle easier than with other methods (Kato et al. 2003). Grafting can be achieved using different chemical techniques such as chemical oxidation, plasma discharge method and UV irradiation, and physical methods, such as radiation polymerization (Kato et al. 2003), as previously discussed (see entry, Surface modification: chemical treatment). The part of the work described here focuses on free radical chain polymerization via chemical oxidation due to its nondestructive nature, relatively low economic feasibility, and ease of covalent bonding, which leads to the potential for in situ modification.

A radical is an atomic or molecular species having one or more unpaired electrons. Though they are electron deficient, they are uncharged resulting in different chemistries as compared to those of ionic or even electron species. Apart from very few stable radicals such as nitric oxide ($\text{NO}\cdot$), most radicals are very unstable and reactive making them suitable for initiating chemical reactions with typical stable polymeric surfaces. The amount of extra stabilization that adjacent lone pairs, π bonds, and σ bonds provide to

radicals is not as great as that which they provide to carbocations. The reason is that the interaction of a filled atomic molecular orbital with an empty atomic orbital (as in carbocations) puts two electrons in a molecular orbital of reduced energy. In contrast, the interaction of a filled atomic or molecular orbital with a half-filled atomic orbital (free radicals) puts two electrons in a molecular orbital of reduced energy and one electron in a molecular orbital of increased energy as shown in Fig. 1 (Jones 2005).

Pairs of electrically neutral free radicals can be formed via homolytic bond breakage that can be achieved by heating in nonpolar solvents or the vapor phase. All molecular species dissociate into radicals at elevated temperatures. Neutral radicals can also be produced in polar environments through oxidation processes (Jones 2005). Once the free radicals are formed on the membrane surface, due to their extreme reactivity, polymerization proceeds by coupling monomer chains to the membrane surface (Kato et al. 2003).

Radical activation of the polymer surface can be achieved by several of the previously mentioned methods such as chemical exposure, plasma treatment, and irradiation. In the current study, a chemical initiator, sodium persulfate ($\text{Na}_2\text{S}_2\text{O}_8$), was used to produce free radicals on the CA membrane surface. Sodium persulfate, with its excellent solubility in aqueous media

and oxidizing nature, is a suitable agent for CA membrane surface activation and PEG chain propagation on the surface through the reaction between radical species formed as result of persulfate action.

Surface Morphology

► Membrane Morphology

Surface Tension

Paul Melvyn Williams
College of Engineering, Swansea University,
Swansea, UK

Surface tension: The term surface tension refers to the observation that the surface of a liquid behaves as though it were covered with a thin “skin” which resists attempts to puncture it. This property is caused by cohesion of similar molecules and is responsible for many of the behaviors of liquids. In the bulk of the liquid, each molecule is pulled equally in every direction by neighboring liquid molecules, resulting in a net force of zero. The molecules at the surface do not have other molecules on all sides of them and therefore are pulled inward. This creates some internal pressure and forces liquid surfaces to contract to the minimal area. Surface tension has the dimension of force per unit length or of energy per unit area. The two are equivalent. In SI surface tension is measured in N/m or in J/m² (although the more common units in cgs are dynes/cm or erg/cm², respectively).

Sweep Gas in a Membrane Reactor

Giuseppe Barbieri
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The sweep gas is a gas present in the permeate side of a membrane reactor to lower the partial pressure of the permeating species and increase the driving force. This gas should be different from any species produced by the reaction, and permeating the membrane because of its back permeation into the reaction side deflects the reaction.

The permeation driving force, for any permeable species, is a function of the difference of chemical potential on both reaction and permeation sides of the membrane reactor. This is also valid for membrane reactors used for gas-phase reactions where the driving force can be increased operating on partial pressure both increasing the feed one and reducing permeate pressure of the specific chemical species.

Specifically, the partial pressure of a permeating species can be reduced in two ways: reducing the total pressure on the permeate side, applying a vacuum, for instance, and/or using a sweep gas on the permeate side. Both ones have the same effect since they increase the permeation driving force improving, as a consequence, the membrane reactor performance, that is, conversion and, if we're speaking about hydrogen production, the hydrogen recovery on the permeate side. However, depending on the used method, the permeate phase will have a very different composition. It will consist of the only permeable species in the case the vacuum is applied. In the other case, the concentration of the permeable species will be

Sweep Gas in a Membrane Reactor, Fig. 1 Scheme of a membrane reactor showing the four inlet/outlet stream, including the sweep gas one

lowered by the presence of the sweep gas; thus, another separation stage is required for purifying the permeate phase.

In a flow membrane reactor, the sweep stream can flow in co- or countercurrent with respect to the feed stream. The Fig. 1 shows the latter option in the case of methane conversion for hydrogen production.

Marigliano et al. (2003) demonstrated that in hydrogen production from methane steam reforming in palladium-based membrane reactor, a high hydrogen partial pressure on permeate led to a lower methane conversion, but a higher sweep gas flow rate reduces the hydrogen partial pressure increasing, in the meantime, the methane conversion.

The use of a sweep gas results in the dilution of the permeated species concentration (Marigliano et al. 2003). It is a drawback in many production cycles such as hydrogen production since the hydrogen permeating the membrane results diluted and requires a concentration. Few cases, for instance, are exceptions: (a) hydrogen produced for ammonia synthesis is good if diluted with nitrogen in a right feed ratio, and (b) the reaction conversion plays a more significant role than the permeated species.

Sweep Gas Membrane Distillation (SGMD)

Maria Tomaszewska

Faculty of Chemical Technology and Engineering, West Pomeranian University of Technology, Szczecin, Poland

SGMD is a membrane distillation (MD) configuration in which a stripping gas is used as a carrier for the vapor transferred from a warm aqueous feed through a porous hydrophobic membrane. The nature of the membrane prevents from penetration of liquid into the pores; therefore, the liquid/vapor interface is formed at each pore entrance. The volatile molecules evaporate through the membrane pores, and a cold inert gas flowing along the other side of the membrane sweeps the permeate carrying it away from the module. The condensation of the vapor occurs in an external condenser (Fig. 1). The driving force for the mass transfer in SGMD is the difference in the partial pressure of volatile substances on both sides of the membrane. Since in MD heat is transferred from the feed side through the membrane, thus the sweep gas temperature increases considerably along a module. However, SGMD combines a relatively low conductive heat loss through the membrane with a reduced mass transfer resistance. Hence, the resulting high mass transfer coefficients provide higher permeate flux than that in direct contact membrane distillation (DCMD) (using the same membrane).

Sweep Gas Membrane Distillation (SGMD), Fig. 1 Schema of SGMD process

Membranes used in SGMD are porous and hydrophobic, similarly as in other MD configurations. Air, humid air, or dry nitrogen can be used as a sweep gas.

The permeate flux obtained in SGMD can be in the range from ca. 1 to 25 kg/m²h, depending on the membrane type, feed composition, and operating conditions (Khayet and Matsuura 2011). Nonvolatile species present in an aqueous solution are theoretically completely retained in the feed, whereas volatile organic substances are partially transferred through a membrane. The separation performance in SGMD is determined by a vapor/liquid equilibrium and depends mainly on a difference in volatility of components in a mixture. However, the differences in the diffusion rates of components through the gas in the membrane pores should be also taken into account.

For the case when SGMD is applied for treatment of an aqueous solution containing nonvolatile compounds and the permeate is swept away using air or any other neutral gas, the equations describing mass (J) and heat (Q) transfer in DCMD can be adapted (Khayet and Matsuura 2011):

$$J_w = B_w \left(p_{w,f}^0 a_{w,f} - p_{w,p} \right)$$

where B is membrane permeability (depends on membrane properties, e.g., thickness, porosity,

pore size) under the SGMD conditions, p is partial pressure, and a_w is water activity. The superscript 0 denotes pure water, and subscripts w , f , and p refer to water, feed, and permeate, respectively. The $p_{w,f}^0$ and $a_{w,f}$ depend on the feed temperature, whereas $p_{w,p}$ depends on the gas temperature at the membrane surface, respectively.

When volatile compounds are present in a feed, both the water vapor and the molecules of volatile compounds are transferred across a membrane. The separation factor of volatile compound i (α_i) can be calculated as:

$$\alpha_i = \frac{y_{i,p} / (1 - y_{i,p})}{x_{i,f} / (1 - x_{i,f})}$$

where $y_{i,p}$ and $x_{i,f}$ are molar fractions of i species in the gaseous permeate and liquid feed, respectively.

In this case the total SGMD permeate flux (J) (if coupling effects are not considered) can be written as:

$$\begin{aligned} J &= \sum_j B_j \left(p_{j,f}^0 a_{j,f} - p_{j,p} \right) \\ &= \sum_j B_j \left(p_{j,f}^0 \gamma_{j,f} x_{j,f} - f_{j,p} P \gamma_{j,p} \right) \end{aligned}$$

where $\gamma_{j,f}$, $x_{j,f}$, and $f_{j,p}$ are the activity coefficient, the mole fraction in the liquid and gas phase, and the fugacity coefficient of species j , respectively. The subscript j refers to all volatile compounds including water.

Various models were applied for description of mass transfer in SGMD. Nevertheless, it was usually concluded that the transport occurred according to a combined Knudsen/ordinary molecular diffusion mechanism.

The heat transfer in SGMD (Q) is described by the following steps: heat transfer through the liquid boundary layer on a feed side (Q_f), heat transfer through a membrane (Q_m) (through a membrane material and gas-filling pores (Q_c) and with permeate stream Q_v), and heat transfer through the gas boundary layer (Q_p) (Fig. 2).

Sweep Gas Membrane Distillation (SGMD),
Fig. 2 Heat transfer resistances in SGMD

Value of the permeate flux depends on the SGMD operation conditions, e.g., the inlet temperatures and the flow rates of both fluids, i.e., liquid feed and sweep gas, and membrane characteristics. The permeate flux is strongly dependent on a feed temperature because of exponential growth of vapor pressure with temperature. On the contrary, an increase in the sweep gas temperature leads to a decrease of the vapor pressure gradient thus the resultant permeate flux is lower. The major disadvantage of SGMD configuration is a very high increase of the gas temperature along a module.

The permeate flux is practically independent on the feed flow rate. The sweep gas flow rate is a very important parameter. An increase in the permeate flux with sweeping gas flow rate is caused by improved hydrodynamic conditions on the permeate side and a reduction of temperature polarization effect. The thermal efficiency of SGMD is higher than in DCMD because the heat loss by conduction through a membrane is lower (Charfi et al. 2010; Khayet and Matsuura 2011). It was found that the permeate flux is higher for membranes with larger pore size.

Sweep Gas Membrane Distillation (SGMD) Applications

Maria Tomaszewska

Faculty of Chemical Technology and Engineering, West Pomeranian University of Technology, Szczecin, Poland

SGMD is the least frequently used configuration of membrane distillation (MD) because the external condenser is required to collect the permeate. Moreover, a little amount of the permeate is collected by a large volume of a sweep gas. Therefore, the system design is complicated and rather expensive.

Similarly as the other MD configurations, the SGMD can be used to treat the solutions containing nonvolatile compounds, such as salts. The salt rejection is practically 100 % and high-purity water can be obtained. However, since the volatile species permeate through the membrane, a more profitable application of SGMD is the removal of volatile organic substances (esters, ethers, chlorinated hydrocarbons, aromatic compounds) or dissolved gases from aqueous solutions. Thus, SGMD can be applied in chemical and petrochemical industries, in biotechnology, or in environmental engineering, where the organic substances have to be recovered/removed from very diluted solutions. Moreover, SGMD can be applied in the cases where DCMD cannot be used due to the risk of the membrane wetting.

Laboratory-scale studies have demonstrated a high potential of SGMD for removal of organic volatile compounds such as ethanol, isopropanol (IPA), and acetone from wastewater (Khayet and Matsuura 2011). A novel SGMD-based micro-separator has been studied for the separation of a mixture of methanol and water. A bioreactor combined with SGMD for ethanol production was also proposed, in order to enhance the ethanol productivity as well as to eliminate the fermentation inhibitors. The produced ethanol was free of bacteria, nutrients, and metabolites (He et al. 2012).

Sweep Gas Membrane Distillation (SGMD) Applications, Fig. 1 (a) SGMD flux and (b) IPA selectivity as a function of feed temperature at various feed concentrations

(Reprinted from Lee and Hong 2001, copyright (2001), with permission from Elsevier)

Sweep Gas Membrane Distillation (SGMD) Applications, Fig. 2 (a) Effect of feed temperature and (b) flow rate of sweep gas on ammonia removal using SGMD, feed

flow rate 250 mL/min (Reprinted from Xie et al. 2009, copyright (2009), with permission from Elsevier)

SGMD was applied for treatment of IPA aqueous solutions (below 10 wt.%). The influence of feed temperature on the selectivity and permeate flux is presented in Fig. 1. It was found that the selectivity decreased with an increase of sweep gas flow rate and with IPA concentration in a feed. Moreover, MgCl₂ addition to the feed increased

significantly IPA selectivity, with small reduction of the total permeate flux (Lee and Hong 2001).

High effectiveness (97 %) of SGMD during the removal of ammonia from synthetic industrial wastewater (100 mg/l, pH 11) was also found (Fig. 2). At higher feed temperature, the permeate flux significantly increased, but the selectivity of

Sweep Gas Membrane Distillation (SGMD) Applications, Fig. 3 The experimental results and theoretically predicted values of aroma fractions recovery by SGMD

(Reprinted from Bagger-Jørgensen et al. 2011, copyright (2011), with permission from Elsevier)

ammonia was reduced. For membranes with smaller thickness and larger pore size, the mass transfer coefficient of ammonia was higher, whereas its selectivity was lower. The pH of ammonia solution was very important for its separation (Xie et al. 2009).

Another SGMD application can be an industrial fruit juice processing. Successful experiments were carried out using SGMD for the concentration of sucrose solutions as a model fruit juice (Khayet and Matsuura 2011). SGMD was also used for the recovery of black currant and cherry juice aroma compounds from a model solution and for the retention of anthocyanins in the juice. An increase in the feed temperature improved the aroma flux; thus, their concentration in the permeate was elevated. The highest concentration factors for highly volatile aroma compounds were in the range of 12.1–9.3 (black currant juice) and 16.3–13.0 (model solution). In the case of a black currant juice, the amount of recovered aroma was 73–84 vol.% for the highly volatile compounds (Fig. 3). However, during the concentration of juice, a part of anthocyanins and polyphenols in black currant juice was lost due to

the degradation of anthocyanin by oxidation (Bagger-Jørgensen et al. 2011).

Tapping Mode

Nidal Hilal

Centre for Water Advanced Technologies and Environmental Research (CWATER), College of Engineering, Swansea University, Swansea, Wales, UK

There are many different imaging modes available for the AFM, providing a range of different information about the sample surfaces being examined. However, for simplicity the most common modes will be considered here. In Fig. 1 the force regimes under which the main imaging modes occur are illustrated schematically. In this figure the interaction forces are sketched as the probe approaches and contacts the surface, with distance increasing to the right. At large separations there are no net forces acting between the probe and sample surface. As probe and surface approach each other, attractive van der Waals interactions begin to pull the probe toward the surface. As contact is made, the net interaction becomes repulsive as electron shells in atoms in the opposing surfaces repel each other. In this diagram the repulsive forces are shown as being positive and attractive forces negative.

Intermittent, or tapping, mode of imaging was developed (Hansma et al. 1993, 1994; Zhong et al. 1993) to overcome the limitations of contact mode imaging (Bowen and Hilal 2009). Here the cantilever is allowed to oscillate at a value close to

its resonant frequency. When the oscillations occur close to a sample surface, the probe will repeatedly engage and disengage with the surface, restricting the amplitude of oscillation. As the surface is scanned, the oscillatory amplitude of the cantilever will change as it encounters differing topography. By using a feedback mechanism to alter the z height of the piezo and maintain constant amplitude, an image of the surface topography may be obtained in a similar manner as with contact mode imaging. In this way lateral forces as the probe is scanned across the surface are greatly reduced, compared with the contact mode.

When using tapping mode in air, capillary forces due to thin layers of adsorbed water on surfaces have to be overcome, as well as any other adhesive forces which may be present. If the restoring force of the cantilever due to its deflection is insufficient to overcome adhesion between the probe and the surface, then the probe will be dragged along the surface in an inadvertent contact mode. As a result, for this mode in air, the spring constants of AFM cantilevers are by necessity several orders of magnitude greater than those used for either tapping mode in liquid or contact mode (typically in the range of $0.01\text{--}2\text{ N m}^{-1}$ for contact mode to $20\text{--}75\text{ N m}^{-1}$ for tapping in air).

As surfaces with different mechanical and adhesive properties are scanned, the frequency of oscillation will change causing a shift in the phase signal between the drive frequency and the frequency with which the cantilever is actually

Tapping Mode, Fig. 1 Diagram illustrating the force regimes under which each of the three most common AFM imaging modes operate. Contact mode operation is in the repulsive force regime, where the probe is pressed against the sample surface, causing an upward deflection of

the cantilever. Noncontact mode interrogates the long range forces experienced prior to actual contact with the surface. With intermittent contact, or tapping mode, the probe is oscillated close to the surface where it repeatedly comes into and out of contact with the surface

oscillating (Schmitz et al. 1997; McLean and Sauer 1997). This phenomenon has been used to produce phase images alongside topographic images, which are able to show changes in the material properties of the surfaces being investigated. However, while the qualitative data this provides is useful, it is difficult to extract quantitative information from the phase images due to it being a complex result of a number of parameters, including adhesion, scan speed, load force, topography, and the material, especially elastic, properties of the sample and probe (McLean and Sauer 1997; Loos 2005).

Temperature Polarization

Maria Tomaszewska

Faculty of Chemical Technology and Engineering, West Pomeranian University of Technology, Szczecin, Poland

In the membrane distillation (MD) process, mass and heat transfer through a hydrophobic microporous membrane occurs simultaneously. The mass transfer proceeds through the membrane pores, whereas the heat is transferred both through the pores (with permeate flux) and across the membrane material.

According to the mechanism of MD, water and volatile solutes present in the feeding solution evaporate from the liquid–vapor interface on the

Temperature

Polarization, Fig. 1 Heat

and mass transfer through the membrane in DCMD configuration

feed side of a hydrophobic membrane. The vapor is transferred through the membrane pores and subsequently is either condensed in the stream of cold distillate flowing along the membrane or removed from a membrane module on the distillate side.

Since the mass transfer in MD occurs in a vapor form, the energy for water evaporation has to be supplied from the hot feed to the liquid-membrane interface. When the vapor is condensed at the vapor-liquid interface on the cold side of the membrane, the energy (heat) is released. Moreover, a part of energy accumulated in the hot feed is transferred across the membrane material and the gas trapped in the pores. Around 50–80 % of energy is consumed as the latent heat for the water vapor production, whereas 20–40 % is lost by conduction through the membrane (Alkhudhiri et al. 2012). Thus, the temperatures in the bulk feed and permeate solutions (T_f and T_p , respectively) differ from the corresponding temperatures at the membrane/solution interface where vapor-liquid transition occurs (T_{mf} and T_{mp}), which is presented in Fig. 1. This phenomenon is termed as **temperature polarization (TP)**. A decrease of temperature on the feed side reduces the partial vapor pressure being in equilibrium with the liquid phase, whereas higher temperature on the permeate side increases the

partial pressure which results in a reduction of both the driving force (i.e., vapor pressure difference ($p_f - p_p$)) and the permeate flux through MD membranes. The boundary layers are formed at the membrane surfaces both on the feed and permeate sides. This causes an additional resistance, besides a membrane resistance, and is considered as the limiting factor of the mass transport efficiency (Khayet 2011).

Regardless of MD configuration, the mass and heat transport through the membrane as well as the effects of temperature boundary layers at the membrane surfaces which affected the magnitude (extent) of **TP** should be taken into account. The most severe, negative influence of **TP** can be expected in DCMD, where a substantial resistance of the boundary layers present in a liquid form on the both sides of the membrane can be observed.

In the vacuum membrane distillation (VMD) process, the vacuum provides insulation against conductive heat loss through the membrane, and the boundary layer resistance on the permeate side is negligible. In the air gap membrane distillation (AGMD), a stagnant air is introduced between the membrane and the condensation surface which reduces a heat loss by conduction. However, an additional resistance to mass transfer is generated. In sweep gas membrane distillation (SGMD), an inert gas is used to sweep the vapor at the

permeate side of a membrane. The gas barrier reduces the heat loss, but the conditions are not stationary, and the mass transfer coefficient increases (Alkhudhiri et al. 2012).

TP in MD can be reduced by using appropriate membranes, which are characterized by:

- As low as possible, thermal conductivity of the membrane material to reduce heat loss through conduction
- Optimized thickness, because it is inversely proportional to the rate of mass and heat transport through the membrane
- High porosity, since the conductive heat transfer coefficients of the gases entrapped in the pores are an order of magnitude smaller than those of the used membrane materials

TP can be also diminished when the flow rate of streams along the membrane surface reduces the boundary layer thickness.

Temperature Polarization Coefficient (TPC)

Maria Tomaszewska

Faculty of Chemical Technology and Engineering, West Pomeranian University of Technology, Szczecin, Poland

In all membrane distillation (MD) configurations, the mass and heat transfer takes place simultaneously. In the process the water vapor is transferred through a porous hydrophobic membrane. In order to achieve evaporation of water at the membrane-liquid interface, the heat has to be

supplied from the warm feed. In direct contact membrane distillation (DCMD), the vapor condenses at the cold membrane-liquid interface, and the heat is released to a cold distillate. This creates temperature gradients in the boundary layers adjacent to both sides of the membrane. The temperatures in the bulk solution (T_f and T_p) are different from the corresponding values on the membrane surfaces (T_{fm} and T_{pm}). The heat transfer across the boundary layers is often considered as the limiting factor for mass transfer in DCMD. The temperature polarization coefficient (TPC) (Θ) is generally used as a measure of the magnitude of the boundary layer resistance in relation to the total heat transfer resistance. TPC can be also written as a function of the heat transfer coefficients in the thermal boundary layers:

$$\begin{aligned}\Theta &= (T_{fm} - T_{pm}) / (T_f - T_p) \\ &= 1 - H/h \text{ where } 1/h = 1/h_f + 1/h_p\end{aligned}$$

The h_f and h_p are the heat transfer coefficients in the feed and permeate boundary layers, respectively, and H is the global heat transfer coefficient of the MD process.

TPC indicates a reduction in the effective driving force (vapor pressure difference through the hydrophobic membrane) and has a negative influence on DCMD productivity.

When the thermal boundary layer resistances are reduced, the temperature differences between the liquid-vapor interfaces and the bulk temperatures become close to each other, and TPC approaches to 1. This value can be achieved in a properly designed module, in which the only limitation is mass transfer. For a poorly designed module with high heat resistance of boundary layers, the value of Θ approaches to zero and the process is limited by heat transfer. Usually, for the appropriate designed systems, the value of Θ is in the range of 0.4–0.7.

The performance of DCMD module can be improved by the application of turbulent flow promoters or net spacers to minimize the heat resistance and to increase the heat transfer coefficients of the boundary layers (Khayet and Matsuura 2011). Generally, TPC increases with increasing

feed and permeate flow rates and is reduced with increasing temperature of a feed. Moreover, this coefficient strongly depends on the membrane characteristics. The driving force of MD is decreased by both temperature polarization and concentration polarization. Therefore, they can be combined in one coefficient called the vapor pressure polarization coefficient (Khayet 2011).

TPC defined and calculated for DCMD can be also applied to other MD configurations. In sweep gas membrane distillation (SGMD) and air gap membrane distillation, the heat transfer coefficient on the permeate side is much smaller than that on the liquid side. Therefore, in SGMD the flow rate of sweeping gas controls the process. In vacuum membrane distillation, the boundary layer resistance on the permeate side is negligible. In this case TPC depends on the heat transfer coefficient in feed boundary layer and increases with a membrane permeability (pore size and porosity).

Temperature-Difference-Controlled Evapomeation (TDEV)

Tadashi Uragami
Organization for Research and Development of Innovative Science and Technology (ORDIST),
Kansai University, Suita, Osaka, Japan

As mentioned in the heading of “Evapomeation (EV),” a new EV method for membrane separation that improves upon the shortcomings of pervaporation while keeping the advantages of this technique was developed (Uragami et al. 1988; Uragami and Saito 1989; Uragami 1991, 1993a, b, 1998, 2005, 2006a, b; Uragami 1994). In EV, the temperatures of the feed liquid

Temperature-Difference-Controlled Evapomeation (TDEV), Fig. 1 Principle of temperature-difference-controlled evapomeation (TDEV)

(I) and the membrane surroundings (II) are controlled, and consequently a differential between these temperatures can be established, as shown in Fig. 1. Such an EV method, in which this temperature difference is controlled, is called “temperature-difference controlled evapomeation” (TDEV) (Uragami 1998, 2005, 2006a, b, 2008, 2011; Uragami and Morikawa 1987, 1992; Uragami and Tanaka 1991, 1993, 1994; Uragami and Shinomiya 1991, 1992; Uragami et al. 2002).

In TDEV, when the temperature of the feed liquid was kept constant at 40 °C and the temperature of the membrane surroundings was changed for an aqueous dilute ethanol solution through a dense poly(dimethylsiloxane) (PDMS), the permeation rate decreased but the ethanol to a temperature less than the temperature of the feed liquid concentration in the permeate increased with lowering of the temperature in the membrane surroundings. The decrease in the permeation rate can be attributed to lowering the motion of both the permeating molecules and polymer chains consisting the PDMS membrane. On the other hand, the increase in the ethanol/water selectivity is explained as follows. At first, ethanol and water molecules are vaporized from the feed mixture at higher temperature. When those vaporized molecules come close to the membrane surroundings kept at a lower temperature, the water molecules

Temperature-Difference-Controlled Evapomeation (TDEV), Table 1 Effect of the freezing point on the selectivity of the permeant in the organic liquid mixtures through polymer membranes in TDEV

Membrane	Chitosan	PVC	PDMS
Freezing point of permeant	(CH ₃) ₂ SO/ H ₂ O 18.5 °C > 0 °C	CH ₃ COOH/ H ₂ O 16.7 °C > 0 °C	C ₂ H ₅ OH/ H ₂ O −114.4 °C < 0 °C
Selectivity	H ₂ O	H ₂ O	C ₂ H ₅ OH

are more aggregated than the ethanol molecules (because the freezing points of water and ethanol are 0 and −114.4 °C, respectively). It is very difficult for these aggregated water molecules to be incorporated into the dense PDMS membrane and diffuse through the dense PDMS membrane. However, the ethanol molecules are not aggregated in the range of the temperature in the membrane surroundings under these permeation conditions. The increase in the ethanol/water selectivity is due to the aggregation of water molecules and is significantly governed by the degree of aggregation of the water molecules.

In Table 1, the effect of the freezing point of the permeant in aqueous organic liquid mixtures on the selectivity through some polymer membranes in TDEV in which the feed liquid was kept constant and the temperature of membrane surroundings was changed is summarized. As can be seen from Table 1, the permeant having a lower freezing point in the feed mixture is selectively permeated. In addition, when the membrane has a stronger affinity to the preferentially permeating mixture component, an increase in selectivity can result in TDEV.

Figure 2 shows the effect of the temperature of the membrane surroundings on the permeation rate and the ethanol concentration in the permeate for an aqueous solution of 10 wt% ethanol through a dense PDMS membrane (a) and a porous PDMS membrane (b) in TDEV. In Fig. 2, the temperature of the feed solution is kept constant at 40 °C, and the temperature of the membrane surroundings was changed. As shown in Fig. 2a, b, the tendency of the decrease in the permeation rate decreased, and the increase in

Temperature-Difference-Controlled Evapomeation (TDEV), Fig. 2 Comparison of the permeation and separation characteristics for an aqueous solution of 10 wt% ethanol of a dense PDMS membrane (a) and a porous PDMS membrane (b) in TDEV. Feed liquid is aqueous solution of 10 wt.% ethanol (40 °C)

the ethanol/water selectivity with lowering temperature of the membrane surroundings through these two PDMS membranes was very similar. In spite of the fact that the ethanol/water selectivity in these PDMS membranes was almost equal, the permeation rates through these PDMS membranes were remarkably different, i.e., the permeation rates in a porous PDMS membrane were higher by three orders of magnitude than those of a dense PDMS membrane.

A remarkable difference in the permeation rate between dense and porous PDMS membranes can be attributed to the fact that the permeation through a dense PDMS membrane is due to the

Temperature-Difference-Controlled Evapomeation (TDEV), Fig. 3 Tentative mechanism of the concentration of aqueous ethanol solutions through porous PDMS membrane in TDEV

solution-diffusion model (Binding et al. 1961; Aptel et al. 1974) and that through a porous PDMS membrane is pore flow based on, as shown in Fig. 3.

Temporary Liver Support Systems

► Bioartificial Liver Support System (BLSS)

Tensile Strength

Enrica Fontananova

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Tensile strength, often indicated as **ultimate tensile strength** or **ultimate strength**, is the maximum stress that a material can withstand while being stretched before failing or breaking.

The tensile strength of a membrane is usually measured by a tensile tester registering tensile stress versus strain (i.e., extension per original length) until failing or breaking. At a given temperature the specimen is clamped between two grips and stressed by moving the mobile grip at constant rate of extension, while the fixed grip is connected to a force transducer (Fig. 1).

The tensile strength (TS) is calculated by

$$TS = \frac{F_{\max}}{S}$$

where TS is the tensile strength (Nm^{-2} or Pa); $F_{\max}$ is the maximum stress before specimen failing or breaking (N); S is the initial cross section area of the sample (m^2), i.e., the product of membrane thickness for sample wide. The tensile strength is often reported in Nmm^{-2} or MPa.

Observing a stress/strain curve (Fig. 2) it is possible to distinguish two different regions:

- The region of elastic deformation (ER) corresponding to the linear portion of the curve (slope constant), where a reversible deformation of the material occurs and ends at the elastic limit (D, Fig. 2), at which the slope of the curve starts to decrease.

Tensile Strength, Fig. 1 Image of a membrane specimen clamped between two grips (indicated by a white arrow) during a stress–strain elongation test

- The region of plastic deformation (PR); after the elastic limit, where the slope of the curve decreases considerably and for some materials it resets very quickly in correspondence of the yield stress (C); for others it continues to decrease until the break in the sample (B) which can also take place by stress lower than the maximum registered during the test.

In the elastic region, once stress is removed, the sample returns to original size/shape. In the plastic region permanent deformations are induced by the applied stress.

In addition to tensile strength (A, Fig. 2), other mechanical parameters that can be obtained from a stress-strain test are:

- Breaking point (B, Fig. 2; [Nm^{-2}]): is the strain registered at the failure or breaking of the specimen.

Tensile Strength, Fig. 2 Typical stress–strain curve and the main parameters that can be obtained: *A*: tensile strength (Nm^{-2}); *B*: breaking point (Nm^{-2}); *C*: yield strength (Nm^{-2}); *D*: elastic limit (Nm^{-2}); *E*: modulus of yield (Nm^{-2}); *F*: modulus of elasticity or Young's modulus

(Nm^{-2}); *G*: modulus of rupture (Nm^{-2}); *H*: elongation at yield (%); *I*: elongation at break (%). The yellow zone correspond to the elastic region (ER) and the blue zone to the plastic region (PR)

- Yield strength (*C*, Fig. 2; [Nm^{-2}]): is the stress which corresponds to the first significant drop of the stress–strain curve, when an increase in the deformation does not correspond to a linear increase in stress.
- Modulus of yield (*E*, Fig. 2; [Nm^{-2}]): is the slope of the line joining the origin of the diagram with the yield strength point.
- Modulus of elasticity or Young's modulus (*F*, Fig. 2; [Nm^{-2}]): is the ratio of the stress and the corresponding strain in the elastic region. It represents a measure of the elasticity: the higher the Young's modulus, the greater the rigidity of the sample.
- Modulus of rupture (*G*, Fig. 2; [Nm^{-2}]): is the slope of the line joining the origin of the diagram with the breaking point.
- Elongation at yield (*H*, Fig. 2; [%]): is the increase in elongation (deformation in percentage or relative) at the yield strength point.
- Elongation at break: is the increase in elongation at the rupture of the specimen (*I*, Fig. 2; [%]).

Tensile strength is one of the key factors that influence the industrial application of the membranes because of its impact on long-term

performance of the same. During their operative life, membranes undergo continuous mechanical solicitations during filtration operations, as well as cleaning procedures (e.g., backwashing) and a high tensile strength is a desirable property to increase membrane durability.

The addition of inorganic nanoparticles (e.g., silica, Fe_3O_4 , ZrO_2 , TiO_2 , CdS) to polymeric membranes can cause an increase in tensile strength to some extent because the free motion of polymeric chains can be partly restricted by the intermolecular forces between the polymeric chains and the inorganic nanoparticles (Ng et al. 2013). In particular the exceptional tensile strength of graphitic nanostructures like carbon nanotubes and graphene has been motivating an increasing interest to reinforce polymeric membranes with these additives (Spitalskya et al. 2010; Kuilla et al. 2010; Fontananova et al. 2015). Tensile strengths of carbon nanotubes range from 60 to 150 GPa while the values for graphene monolayers are around 130 GPa, versus typical values of 10–30 MPa of numerous organic polymers (e.g., high-density polyethylene and natural rubber).

Tensile strength can also be enhanced by a chemical and/or physical cross-linking of the

membranes. Of course not only composition but also membrane structure influences the resulting tensile strength.

In the case of crystalline or semicrystalline membrane materials also crystal form, crystallinity, and crystalline morphology can have a relevant impact on the tensile strength (Liu et al. 2013).

Ternary Pd-Alloy Membranes

Thijs Peters

SINTEF Materials and Chemistry, SINTEF, Oslo, Norway

Palladium (Pd) has high solubility and diffusivity of hydrogen and shows therefore great promise as a membrane material for medium to high temperature hydrogen separation (250–550 °C). In pure Pd, however, an α -to- β -hydride phase transition may occur in hydrogen below about 290 °C, and only a few cycles through this transition make the material brittle and must be avoided. By alloying Pd with different elements, the phase transition can be suppressed, and the majority of the work

related to Pd-alloy membranes applies particularly alloys with 20–30 wt.% Ag and 40 wt.% Cu. The drawback is, however, that these alloys are to various degrees prone to poisoning by CO- and sulfur-containing gases leading to reduced H₂ flux or even to a complete membrane failure. Research therefore currently focuses on developing more advanced ternary or quaternary alloys that may be needed to improve the mechanical, thermal, and chemical stability of Pd-based membranes.

The main problems with membrane reliability are related to their corrosion resistance and structural changes that occur during operation. Palladium and Pd-alloys have therefore been alloyed with additional other metals, including Ru, Mo, W, Y, Ta, V, Rh, Nb, Cr, Ni, and Fe, to obtain greater mechanical strength and to inhibit undesired grain growth resulting in an increased temperature stability. Doping Pd with higher melting point metals (such as Ru or Pt) seems to enhance the thermal stability of the membrane. In terms of corrosion resistance, various approaches involving ternary Pd-alloys are being followed. Fcc Pd-Cu membranes are known for their sulfur tolerance but are less permeable than Pd. Several studies have therefore focused on improving the hydrogen flux through Pd-Cu membranes by adding a third element. In this respect, Ag is most particularly interesting since Pd-Ag has a higher hydrogen permeability compared to pure Pd. Another approach is to alloy the high-flux Pd-Ag alloy membrane with ternary elements to enhance the sulfur tolerance without significantly reducing the high permeability of this alloy. The Pd-Ag-Au alloy developed along this route displayed higher initial H₂ permeability than pure Pd and, consistent with resistance to bulk sulfide formation, lower permeability loss in H₂S than pure Pd. This indicates that the addition of small amounts of Au to the high-flux Pd-Ag alloy membrane improves the sulfur tolerance of this alloy and that this could be an interesting approach in the development of high-flux Pd-based alloy membranes with improved sulfur tolerance. Still, however, flux targets remain a challenge for new alloys in large-scale applications in the presence of sulfur impurities.

Tetrazole Group

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

Tetrazoles are a class of heterocyclic compounds consisting of a five-member ring of four nitrogen and one carbon atom. The chemical formula for simplest tetrazole is CN_4H_2 and the chemical structure is represented in Fig. 1.

Tetrazoles have wide range of applications which are currently receiving considerable attention (Butler 1996); therefore, the literature on tetrazole is expanding rapidly. This functional group has a role in coordination chemistry as a ligand (Du et al. 2011), as well as in various materials sciences applications including photography, energetic materials, and membranes (Gomes 2012; Herr 2002; Miyata et al. 2004, 2005). Tetrazole and its derivatives such as 5-aminotetrazole are sometimes used as a component of gas generators in automobile airbags. Extensive work has also been carried out in the field of medicinal chemistry, where tetrazoles are frequently used as metabolically stable surrogates for carboxylic acids (Lin 2005; Pu et al. 2008).

One of the recent researches in the development of novel microporous organic polymers (MOPs) represented that by the introduction of tetrazole groups into highly microporous polymeric frameworks resulted the favorable CO_2 sorption with superior affinity in gas mixtures and selective CO_2 transport by presorbed CO_2 molecules that limit access by other light gas molecules. This proves the importance of tetrazole groups in designing MOP membrane materials for economic CO_2 capture processes (Singh et al. 2006). Proton-conductive and particularly anhydrous proton

conductivity of poly(5-vinyltetrazole)-based composite membranes were also evaluated and found to be efficient not only for intermediate temperature fuel cells but also in solid electrochromic devices (Vyas et al. 1986).

Texture Recognition

Carles Torras Font

Bioenergy and Biofuels, Catalonia Institute for Energy Research (IREC), Tarragona, Catalonia, Spain

Tetrazole Group,

Fig. 1 Chemical structure of tetrazole

There are a variety of methods used to determine the porosity of a membrane, such as mercury porosimetry, microscopy, physisorption, etc. (Mulder 1996; Palacio 1999). And from them, the method that provides more information about

the whole porous structure of a membrane is, probably, scanning electron microscopy (SEM) by obtaining surface and cross-section membrane micrographs (Kools 1998). Often, the pore size, shape, etc. of a membrane are different depending on the position and caused by the process of membrane formation. These variations are considered through several morphological parameters such as regularity, symmetry, etc. (Torras and Garcia-Valls 2004). They imply significant effects to the membrane performance (Torras et al. 2006).

But an inconvenient of SEM technique is that it provides only qualitative results through micrographs (Torras and Garcia-Valls 2004). Thus, it is necessary to interpret the images numerically for a variety of reasons: obtain correlations between membrane morphology and synthesis conditions, between membrane morphology and membrane performance, etc. This can be achieved by modeling the porous structure. There are some methodologies to achieve it, such as fractals (Tam and Tremblay 1993), phase field simulation (Zhou and Powell 2006), or molecular simulation approaches (Chang et al. 2010). Recently texture recognition has also been tested for this purpose with promising results and from SEM membrane micrographs (QUANTS methodology – software) (Torras et al. 2011).

Texture recognition is a field of knowledge proper from computer vision. Texture is a visual sign used in a wide number of computer vision tasks because it allows differentiation between objects or surfaces that appear in the image and have a similar shape or color (Bernard-Michel et al. 2002; Lin and Miller 2000). Unfortunately, texture is one of the signs that are most difficult to model because it is intrinsically noisy by nature, and it is affected by different external factors such as illumination, rotation, or scale, which alter its perception. This complexity has caused an intense research during the last decades (Haralick 1979; Manjunath and Ma 1996; Randen and Husoy 1999), which has allowed the publication of a large number of methods to represent texture. Texture can be visualized within structural patterns of surfaces of natural or artificial objects such as wood, sand, grass, textiles, or skin and measured through surface properties such as roughness, regularity, etc.

By applying texture recognition methodologies with membrane micrographs obtained from SEM (Gabor wavelets, watershed transformation, etc.), it is possible to detect and identify the pores that are present in a micrograph, without user intervention. The result is that an artificial image (a simile of the micrograph) can be obtained and computation of several parameters can be performed, such as number of pores, distribution, porosity, changes of pore size along each direction (and consequently, computation of parameters such as regularity or symmetry), tortuosity, etc. (Torras et al. 2011). The only and main limitation of the method is the resolution of the micrograph (Fig. 1).

In conclusion, a main advantage of applying texture recognition techniques over membrane

Texture Recognition, Fig. 1 Original cross-section membrane micrograph obtained by SEM and results achieved after interpreting the original image with QUANTS software (only showing graphical results)

micrographs is that numerical results of its morphological properties can be obtained in a systematic, reliable, quick, and non-expensive way.

Thermally Induced Phase Separation (TIPS) for Membrane Preparation

Alberto Figoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Phase Inversion (PI) or Phase Separation (PS) is one of the most diffused and versatile methods for preparing polymeric membranes. It is based on the precipitation/solidification of a polymer-rich phase from an initially homogenous system, the casting solution, containing the polymer (P), properly dissolvent in an appropriate substance, named solvent (S) or diluent (D). The thermodynamic basis of phase separation is the existence of a miscibility gap in the P/S system, i.e., an ensemble of conditions such that the polymer is not soluble anymore and starts to precipitate and demix from the solution. There are different methods to induce phase separation; in thermally induced phase separation, or TIPS, polymer precipitation is caused by a decrease of temperature, normally provoked by immersion in a quenching bath. Membrane preparation via TIPS requires the finding of an appropriate diluent or “latent solvent,” i.e., a substance that is not able to dissolve the polymer at room temperature but that behaves as a solvent at temperature close to the polymer melting point. Once obtained a homogeneous system, the solution is cast or extruded to obtain a flat sheet or a hollow fiber membrane; temperature decrease induces phase inversion. Then, it is normally necessary to exchange the polymer diluent with a more volatile substance, as an alcohol, for removing it; finally, the membrane can be dried.

The phenomenological description of TIPS can be done with the aid of binary phase diagrams (Strathmann et al. 2010), which show the boundaries of the stable, metastable, and unstable P/S compositions as a function of temperature. The spinodal curve delimits the unstable region, while the metastable region is enclosed between the spinodal and the binodal curves. When the temperature T_I of a generic homogeneous solution

Thermally Induced Phase Separation (TIPS)

for Membrane Preparation,
Fig. 1 Binary phase diagram describing TIPS

decreases from a point located in the stable region (Point A, Fig. 1) to a point located in the miscibility gap (Point B at T₂), below the spinodal curve, phase separation takes place. The system will separate in two phases (B' and B''), corresponding to the polymer-rich and the polymer-lean phases; they will give rise to the membrane and its pores, respectively.

Membrane formation can take place, in general, via liquid-liquid (L-L) or solid-liquid (S-L) demixing; this depends on several factors, as polymer type and concentration and diluent type. Furthermore, other phenomena as vitrification and gelation may occur.

In L-L demixing, after the system crosses the binodal curve, either spinodal decomposition (SD) or nucleation and growth (NG) can proceed. NG can occur only in the metastable region between the binodal and the spinodal curves; two cases can be distinguished. If phase separation proceeds via NG of the polymer-rich phase in the solvent phase (Metastable region I, in Fig. 1), a structure with poor integrity is obtained. NG of polymer-lean phase in the solid polymer-rich matrix usually gives rise to isolated pores (Metastable region II, in Fig. 1). SD happens when the systems enter directly in the miscibility gap (usually via a sudden cooling) and may result in bicontinuous structures with high interconnectivity. S-L demixing can be observed only for crystalline and semicrystalline polymers, if the polymer crystallization temperature is reached during cooling. Chain-folded lamellae and supramolecular architectures, as axialites and spherulites, can be observed in this case.

TIPS can be applied to prepare membranes from polymers that are difficult to dissolve at room temperature in common organic solvents, as polypropylene. Furthermore, TIPS has been reported as an alternative method for preparing membranes from more soluble polymers, as PVDF, which can be used also in other techniques as non-solvent-induced phase inversion.

Thermopervaporation (Thermo-PV)

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Pervaporation is a membrane separation process which is based on difference of vapor pressure as driving force. It is a well-established tool for

Thermopervaporation (Thermo-PV),

Fig. 1 Concept of thermopervaporation (Eva et al. 2010)

component recovery from the aqueous phase. Nowadays, pervaporation is usually performed industrially with vacuum as driving force. Vacuum pumps are switched periodically to remove non-condensable gases. For some actual production process, it is unfavorable (Volkov and Bortisov 2012). In vacuum operation only a small pressure loss can be allowed at the permeate side, because an increase in partial downstream pressure influences flux and selectivity negatively. Since large apparatus volumes are necessary, leakage problems may occur, oxygen might diffuse into the apparatus, which would lead to oxidation (Franken et al. 1990).

Thermopervaporation is also called thermopervaporation or thermo-PV. It overcomes the drawbacks of vacuum pervaporation. A reduced partial pressure at the permeate side can also be gained by a temperature difference between feed side and permeate side of the membrane. Based on this technology, it is possible to integrate the condensation energy for direct heating of the feed during pervaporation in one single module. Thermopervaporation is a new concept for pervaporation that benefits from small distances in a membrane module to recover internal heat to the most.

The thermopervaporation process (shown in Fig. 1) aims at making effective use of the

condensation energy of pervaporation vapors. The energy comes from heating the feed. Shortening the vapor transport distances can make the most use of the energy. The initial feed stream (F) enters the module in the condenser at temperature T_1^1 (heat resistance in the condenser has been neglected). The feed is heated up to T_2^1 using enthalpy of condensation of the permeate (P). Then the feed temperature is further increased to T_2^0 by means of an external heat source. There are resulting vapor pressure differences between feed and permeate side of the membrane, so a fraction of the feed permeates the membrane as a vapor and condenses on the condenser plate (Eva et al. 2010). There are many differences between thermopervaporation and pervaporation, which are shown in Table 1.

With the thermopervaporation concept, it is possible to recover heat during pervaporation process in an efficient manner. The process has been established using ethanol separation. Thermo-PV can be operated using low-cost heat (80–100 °C), which is effective in actual production. Besides, the experiments were carried out in a small and suboptimally configured module; results showed that this concept has great potential for commercial applications (Eva et al. 2010).

Thermopervaporation (Thermo-PV), Table 1 Features of thermopervaporation in contrast with pervaporation (Nitta et al. 1986)

Principle	Model	Thermopervaporation	Pervaporation
			
Membrane	Mechanism	Evaporation to permeation	Permeation to evaporation
	Driving force	Temperature (steam pressure) difference	Pressure difference
	Material	Hydrophobic	Hydrophilic
	Structure	Porous	Nonporous
Operation pressure		Normal pressure	Evacuation
Operation temperature		Less than boiling point	Room temperature

Thermoresponsive Membrane Surfaces

Liang-Yin Chu

Membrane Science and Functional Materials Group, School of Chemical Engineering, Sichuan University, Chengdu, Sichuan, China

Thermo-responsive membrane surfaces (also called thermosensitive membrane surfaces) are membranes with thermo-responsive/thermo-sensitive surfaces prepared by grafting or coating thermo-responsive/thermo-sensitive materials onto the membrane surface by certain chemical or physical methods. The substrate membranes provide mechanical strength and dimensional stability, while the conformational changes of the grafted thermo-responsive polymers on the membrane surfaces result in the thermo-responsive characteristics. The surface wettability characteristics and the membrane resistance as well as transmembrane permeability of such membranes can be controlled or adjusted by self-regulation according to the responsive conformational change of the grafted or coated thermo-responsive materials on the membrane surfaces. Because there are numerous cases in which environmental temperature fluctuations occur naturally, and the environmental temperature stimuli can be easily designed and artificially controlled, much attention has been focused on thermo-responsive

membrane surfaces. Such membranes can be used for both controlled release and advanced separation by utilizing the thermo-responsive conformational change of the functional surface layer (Chu 2011).

Various grafting techniques, including chemical grafting, plasma-induced grafting, radiation-induced grafting, and so on, can be employed to prepare thermo-responsive membrane surfaces by grafting thermo-responsive polymers onto the membrane surfaces. According to the location of grafted polymers on the membranes, thermo-responsive membrane surfaces can be classified as surface-covering model (Fig. 1a), pore-covering model (Fig. 1b, d), and pore-filling model (Fig. 1c) (Chu et al. 2011). For the pore-covering and pore-filling models (Fig. 1b–d), the effective membrane pore sizes can be self-regulatively adjusted by the thermo-responsive volume phase transition behaviors of the grafted thermo-responsive materials, i.e., the grafted thermo-responsive materials can act as smart valves that respond to environmental temperature stimuli.

Poly(*N*-isopropylacrylamide) (PNIPAM) is a popular thermo-responsive polymer. It shows a distinct and reversible phase transition at the lower critical solution temperature (LCST) around 32 °C. PNIPAM-based polymers are usually used to fabricate thermo-responsive membrane surfaces (Fig. 1a–c). When the environmental temperature is lower than the LCST, the PNIPAM-based materials exhibit a swollen and hydrophilic state; however, when the temperature is higher than the LCST, the PNIPAM-based materials show a shrunken and hydrophobic state. By such thermo-responsive conformational change of the membrane surface layer, the surface wettability characteristics and the membrane resistance as well as transmembrane permeability of the membranes can be self-regulatively controlled or adjusted according to the environmental temperature change (Chu 2011).

Interpenetrating polymer networks (IPNs) of poly(acrylamide) (PAAM) and poly(acrylic acid) (PAAC) are featured with a thermo-responsive volume phase transition characteristic that is the reverse of that of PNIPAM, i.e., the swelling of PAAM/PAAC-based IPNs is induced by an

Thermoresponsive Membrane Surfaces,

Fig. 1 Schematic illustration of thermo-responsive membrane surfaces grafted with responsive materials possessing thermo-induced shrinking (a–c) and thermo-induced swelling behaviors (d). (a) Surface-covering model, (b, d) pore-covering model, and (c) pore-filling model

increase rather than a decrease in temperature. Therefore, the thermo-responsive membrane surfaces constructed from PAAM/PAAC-based IPNs are featured with negatively thermo-responsive characteristics (Fig. 1d) (Chu et al. 2005). When the environmental temperature is lower than the upper critical solution temperature (UCST) of the PAAM/PAAC-based IPN gel, the IPN hydrogels retain a shrinking state. On the other hand, when the environmental temperature is higher than the UCST of the IPN gel, the IPN hydrogels retain a swelling state. For the pore-covering model (Fig. 1d), the effective membrane pores change from an “open” situation into a “closed” situation when the temperature increases from one that is below the UCST to another that is above the UCST.

Thin-Sheet Zeolite Membranes

Wei Liu

Energy and Environment Technology Directorate,
Pacific Northwest National Laboratory, Richland,
WA, USA

Zeolite materials possess some unique properties, such as molecular-sieving functions, excellent chemical and thermal stability, and low costs. Today, zeolites are used in a variety of catalytic reaction and adsorption separation processes. They are a very attractive class of materials for membrane usage. A large number of scientific articles and patent applications have been published on zeolite membranes for recent two

Thin-Sheet Zeolite Membranes, Fig. 1 Design concept of thin-sheet zeolite membranes

decades. The feasibility of making zeolite membranes and their unique molecular-sieving functions was demonstrated in the late 1990s and early 2000s, which includes those common zeolite frameworks consisting of SiO_2 , Al_2O_3 , and Na_2O , such as NaA, X-type, Y-type, ZSM-5, silicalite, and mordenite. For example, the flux and selectivity of a zeolite membrane was reported to be one to two orders of magnitude higher than the polymeric membranes for solvent dehydration (Morigami et al. 2001).

Zeolites are ceramic-type materials, and self-supported zeolite membranes are too fragile to be made as large sheets (or plates). Thus, zeolite membranes are typically grown on a porous support structure. Ceramic disks and tubes have been used in most literature studies so far. Occasionally, sintered metal tubes and frits were used. Those supporting materials serve well for the purposes of fundamental studies and proof of concept experiments. For actual membrane product development, however, novel product designs and manufacturing processes are needed to produce large zeolite membrane areas suitable for industrial applications at a cost competitive with existing separation technologies.

Ceramic tube-supported zeolite membranes are now commercially available. These tubes have a

length about 1 m and outer diameter from 1.0 to 3.0 cm. A number of membrane tubes can be bundled together to form a membrane module or separation device. Those zeolite membranes are demonstrated at pilot and small-scale commercial plants for dehydration of alcohols and organic solvents. However, their cost (Caro and Noack 2009), which ranged from \$1,000 to 3,000/ m^2 , is too high to be used widely. In addition, a great number of membrane tubes are required for large-scale industrial processes, which present significant challenges to engineering and installation of membrane separation equipment. For example, it is estimated that about 70,000 of membrane tubes are needed for ethanol dehydration in a medium-size ethanol plant of 150 million liters per year production capacity. Instead of a single hole, several holes are made into one membrane tube to achieve incremental improvement to the membrane area packing density.

One approach to address the cost and membrane area problems is to make zeolite membranes like polymeric membrane sheets. Spiral wound polymeric membranes are made at fairly low costs and used in large-scale seawater desalination. The design concept of thin-sheet zeolite membranes is illustrated in Fig. 1. One critical challenge is the support structure. Thinness of

the support sheet is necessary to reduce material consumption, membrane weight, and transport resistance. Thin sheets also enable package of large membrane areas in a given volume, i.e., obtaining high membrane area packing density.

As general requirements of a membrane support, the support sheet needs to be highly permeable so that mass transport through the support would not present a significant resistance for most separation applications, and the support sheet needs to be sufficiently strong to provide the mechanical strength for the membrane sheet to withstand a pressure gradient under separation conditions for a long time. The specific requirements pertinent to zeolite membrane preparation are (i) stability under zeolite membrane growth and preparation conditions, (ii) uniform surface pore structures at micro- and sub-micrometer levels, and (iii) stability under the zeolite membrane separation conditions. The growth of a zeolite membrane typically occurs in a strong basic solution at temperatures ranging from 60 °C to 180 °C. After growth, posttreatment sometimes is needed for the removal of templates and opening of zeolite pores. The possible post-treatment methods are oxidation in an O₂ gas environment at high temperatures, oxidation in plasma or ozone gas environment at moderate or low temperatures, and solvent extraction. Having a uniform surface pore structure at micro- and sub-micrometer levels is necessary for deposition of a thin, continuous zeolite membrane layer on the support. It is obvious that a continuous zeolite membrane less than 10 μm thick cannot be formed on a support surface of pores or defects larger than 10 μm. The zeolite membrane can work under separation conditions that could be problematic to polymeric materials, such as in hydrocarbon and organic solvent media and at high temperatures (relative to environment). Thus, the support sheet needs to be stable under separation conditions so that application and performances of the zeolite membrane would not be compromised by the support. Finally, the support sheet needs to be low costs.

No commercially available materials could be found yet when the above criteria were applied to the selection of a suitable support sheet. Porous

ceramic disks work well as a zeolite membrane support but have not been made as thin, strong, inexpensive sheets yet. Sintered metal plates meet the requirements of mechanical strength and chemical and thermal stability. But they are too thick and too expensive. On the other hand, metal foams and metal meshes have the pore opening too large to be deposited with a thin, continuous zeolite membrane layer. Micro- and ultrafiltration polymeric membranes have adequate surface pore structures but fall short of chemical and thermal stability. No report on formation of high-performance zeolite membranes on a polymeric support has been found yet.

Thin porous metallic sheets have recently been developed that can meet all the above criteria (Liu et al. 2011a; Liu and Canfield 2012). The thin-metal sheets made of Ni, Ni alloys, and steels possess the physical and chemical properties of those metallic materials and provide suitable pore structures for the preparation of a thin layer of zeolite membranes. These metal sheets are made of inexpensive metal oxide raw materials and have large potential for mass production at low costs. As a reference, steel sheets and plates are produced at a price as low as \$1/kg. It was demonstrated that zeolite membranes can be directly prepared on such supports by secondary growth methods (Liu et al. 2011b). The secondary growth consists of two basic process steps: seeding and growth. The support surface is first coated with a layer of small crystals of targeted zeolite framework that act as a seed for zeolite crystal growth. The seed coating also helps smoothening of the support surface. Then, a continuous layer of intergrown zeolite crystals is formed by hydrothermal growth of the seeded support under suitable conditions. Thin-sheet zeolite membranes grown on such a support are illustrated with a NaA membrane in Fig. 2. The 50 μm-thick porous Ni alloy sheet is strong enough to be self-supported and flexible enough to bend and shows uniform surface pore structures. After membrane growth, the sheet surface changes its color from metallic gray to darken glassy luster. A dense and continuous membrane layer comprising intergrown zeolite crystals is formed on the metallic support surface. No cracks and pinholes

Thin-Sheet Zeolite Membranes, Fig. 2 NaA zeolite membrane grown on 50 μm -thick porous Ni sheet support

are seen. Although there are different sizes and shapes of crystals on the membrane, a pure NaA crystal phase is confirmed by X-ray diffraction analysis. It is worth noting that the zeolite membrane shows excellent adhesion onto the support, which is largely attributed to the thinness of the zeolite membrane layer. The zeolite membrane is so thin that the membrane-grown sheet behaves similar to the bare metal sheet, strong and flexible.

The thin-sheet design paves the way for mass production of zeolite membranes at competitive cost. Materials used to make the metal sheet support and prepare zeolite membranes are typically inexpensive commodity products. By making thin-sheet membranes, the raw materials become a minor cost factor. The membrane cost will be largely determined by the preparation process costs. Current planar sheet or plate products, such as papers, metal foils, glass, and polymeric membranes, are manufactured in large bulk quantities at fairly low costs. It is expected that the thin-sheet zeolite membrane can be mass produced by utilizing automated, high-throughput sheet-to-sheet-type manufacturing processes.

The thin sheet enables fabrication of membrane modules or membrane separation

equipment with maximum membrane area and/or minimal mass transfer resistance from bulk to membrane surface. A cross-flow planar module (Fig. 3) is used to illustrate the making of a separation device with the thin-sheet zeolite membrane. An array of membrane sheets is packaged together to form respective feed and permeate channels by the use of proper backing and spacing materials. The sweep (or permeate) and feed (or process) streams are separated by the membrane sheet and flow in perpendicular directions. The membrane surface per unit volume (SA_V) of the stack for this module design can be estimated by the following equation:

$$SA_V = \frac{1}{0.5L_p + 0.5L_F + L_m}$$

where L_p , L_F , and L_m are permeate (or sweep) channel spacing, feed (or process) channel spacing, and membrane thickness, respectively. If $L_p = 1 \text{ mm}$, $L_F = 1 \text{ mm}$, and $L_m = 0.05 \text{ mm}$, SA_V can be $952 \text{ m}^2/\text{m}^3$. Using small channel spacing reduces the mass transfer resistance from bulk to membrane surfaces and increases the membrane area packing density.

In summary, zeolite membranes supported on a thin porous metal sheet are compared to other

Thin-Sheet Zeolite Membranes, Fig. 3 Package of thin membrane sheets into a working module for cross-flow separation and mass transfer

Thin-Sheet Zeolite Membranes, Table 1 Comparison of thin-sheet zeolite membranes to other membrane products

Material	Application	Cost	Characteristics
Polymer	Various commercial products from microfiltration, ultrafiltration, and nanofiltration to molecular separation	Fair	Working well in water medium at ambient or room temperatures
Hollow fiber			
Sheet	~\$10 billion/year global market		Stability issues at high temperatures and in organic solvents or oil
Ceramic	Some specialized applications	High	Tolerance to organics
Tube	A few hundred million \$/year market		Excellent thermal stability
Monolith			Fragile
Metal	Some specialized applications with limited market penetration	High	Ductile and strong
Tube			Tolerant to organics
Thin-sheet zeolite/metal membrane	Porous metal sheet as micro- and ultrafiltration membrane	Fair	Fair thermal stability
	Zeolite membranes for a number of important molecular separation processes		Advantages of metal and zeolite materials
			Module package like polymeric sheets

membrane materials and products in Table 1. This hybrid membrane technology is expected to preserve unique properties possessed by the zeolite and metallic materials and eliminate their shortcomings at the same time. Thus, the hybrid thin-sheet membrane can provide performance and cost advantages that are not achievable using individual materials alone. There is a great opportunity to further develop this membrane technology for various applications and to expand the design concept to other material systems.

3D-Imaging Methods for Membranes

Gonzalo Prieto
Max-Planck-Institut für Kohlenforschung,
Mülheim an der Ruhr, Germany

Synonyms

Three-dimensional (3D) microscopy methods;
Tomographic microscopy methods

Three-dimensional (3D) microscopy methods (also known as tomographic microscopy methods) (Van Tendeloo et al. 2012) are imaging techniques which provide three-dimensional visualization of the internal structure of solid materials. They are employed to investigate the inner architecture of a wide range of membranes. *Tomography*, from Ancient Greek terms *tomos*

(slice) and *grapho* (to write, to record), refers to the possibility of mapping internal sections of the studied object and thereby reconstructing its 3D structure. Most tomographic methods, e.g., those discussed in this entry except from *Atom-probe tomography*, can be divided into two main groups depending on their working principle. Some methods rely on recording a series of two-dimensional (2D) projection images of the sample under different observation angles. Other tomographic techniques rely on the acquisition of sectional views of several, generally parallel, internal planes of the material. Figure 1 depicts schematic representations of the working principle of tomographic imaging methods based on projection (Fig. 1a) and sectional (Fig. 1b) 2D images (*micrographs*). While projection-based methods are nondestructive, i.e., the sample specimen is preserved, some section-based methods are destructive as they rely on mechanical slicing or erosion of thin layers of the material being imaged. The collection of two-dimensional *micrographs*, either projections or single-plane sectional views, is then aligned, often with the help of fiducial markers added onto or next to the sample specimen, and processed with dedicated mathematical algorithms (Herman and

3D-Imaging Methods for Membranes, Fig. 1 Schematic representation of the working principle of tomographic imaging methods based on (a) projectional 2D views and (b) inner-sectional 2D views

3D-Imaging Methods for Membranes, Fig. 2 (a) Plot representing the typical ranges of voxel size and volume of sample inspected in a single experiment for several tomographic imaging methods (Adapted from Uchic et al. 2007); (b) surface-rendered 3D view of a

reconstructed X-ray computed tomogram of a microfiltration membrane (Adapted from Reingruber et al. 2011). *Left side* shows a distance map, and *right side* a tube-type representation of the membrane porosity

Joachim 2014) to reconstruct the internal structure of the solid sample in three dimensions. Such reconstruction is named *tomogram*.

In the following, selected tomographic imaging methods of particular interest to investigate membranes are defined. For these methods, Fig. 2a indicates characteristic ranges for the size of the voxels, i.e., the most elemental unit in a tomogram (equivalent to a pixel in a 2D image), as well as for the volume of sample which can typically be examined in a single experiment. As observed there, the highest is the resolution of the method, i.e., the smaller is the voxel size, the higher is the local character of the technique, i.e., the more limited is the volume of material from which information can be gathered in a single experiment.

Atom-probe tomography (APT) is a 3D-imaging method with atomic resolution and elemental sensitivity, i.e., it does provide information about the chemical composition of the sample studied. Unlike the rest of the tomographic methods considered in this entry, the imaging principle of APT does not involve manipulation of radiation. Experimentally, the sample specimens must be shaped in the form of a sharp tip. The specimen is then exposed to strong electric field pulses which are capable of overcoming the atom-bonding forces in the solid, causing ionization and vaporization of atoms from the surface

of the sample. APT is therefore a destructive imaging method. The emitted ions are subsequently accelerated in the electric field and projected onto a position-sensitive detector which identifies the nature of each detected ion by its time-of-flight from the surface of the specimen to the detector (related to the charge-to-mass ratio of the ion) and reconstructs its position in the original specimen from its point of impact on the detector surface. Through successive evaporation of several layers of atoms from the sample surface, the method allows reconstructing a 3D view of the processed sample, providing atomic scale and elemental information on its structure.

Electron tomography (Frank 2008), also known as 3D transmission electron microscopy (3DTEM), is the three-dimensional version of transmission electron microscopy (TEM). This is a representative projection-based, nondestructive imaging method. Experimentally, a collection of 2D projections (*micrographs*) of the sample is recorded upon tilting the specimen in the transmission electron microscope in a range of angles along either a single or more rotation axis. In the classical version of the method (bright-field ET), each projection image is generated by recording the attenuation of electrons as a function of the position within the illuminated sample specimen. Alternative imaging methods involve rastering the

sample with an electron beam and recording electrons, not transmitted through, but scattered from the specimen at high angles (tomographic high-angle annular dark-field scanning transmission electron microscopy, HAADF-STEM) (Pennycook and Nellist 2011). Features down to the nanometer, in some instances even atomic, scale can be imaged for thin sample specimens, typically less than 400 nm thick in the direction of the illumination beam.

FIB-SEM tomography, also known as tomographic FIB-SEM, is exemplary of sectional-based, destructive imaging methods. To be imaged, the solid specimen is previously spattered with metal overlays to increase sample conductivity. A trench is first carved on the upper surface of the sample with a focused ion beam (FIB). Also the FIB is used later to remove thin parallel layers of material, exposing cross sections of the internal structure of the specimen which are consecutively imaged with a scanning electron microscope (SEM). The resulting stack of SEM *micrographs* of parallel internal planes of the sample is then aligned and processed to reconstruct the internal structure of the volume of sample processed with the FIB. Typically sample volumes in the range of 1–50 μm^3 can be studied in a single experiment, with 3D-imaging resolutions down to 10–30 nm, being the limiting factor of the resolution of the FIB-milling process.

X-ray tomographic microscopy (XTM), also known as X-ray microcomputed tomography (μCT) (Stock 2009), is based on recording a collection of 2D projections of the sample specimen. Similar to the case of ET, each projection image is generated by recording the attenuation of, in this case, X-rays as a function of the position within the illuminated sample specimen. The collection of projections is recorded typically via precise rotation of the sample while keeping the X-ray source and detector stationary. The highest spatial resolution, down to sub-micrometer levels, is achieved with high-intensity X-ray sources in synchrotron facilities.

Confocal scanning microscopy (CSM) (Paddock 1999) is an optical imaging method, hence based on the detection of photons. In contrast to conventional optical microscopes, in

confocal optical microscopes, the sample is illuminated by a single point of light, generally from a laser source, and a pinhole is located in front of the detector allowing the detection of exclusively “in-focus” light originating via, e.g., a fluorescence process from a selected internal plane of the sample. Sequential imaging of several internal planes, at different heights along the sample, allows the 3D reconstruction of its internal structure. Such “optical sectioning” approach could be regarded as a nondestructive analog of the working principle of FIB-SEM tomography.

Most of these tomographic microscopy methods have recently become important diagnostic tools in the design and assembly of a wide array of technological membranes. The suitability of each tomographic method to investigate different structural features in modern membranes is closely linked to their inherent spatial resolution.

The chemically sensitive, atomic-scale information offered by APT makes it suitable to study grain boundary compositions and phase segregation phenomena in dense ceramic or alloy-type membranes. ET permits visualization of nanometer-sized objects within a continuous matrix and has been applied to investigate the internal structure of membranes based on microporous silica doped with metal nanoparticles, which find application in high-temperature hydrogen separation processes (Yoshida et al. 2009). FIB-SEM tomography, with a 3D resolution down to few tens of nanometers, allows three-dimensional visualization of the most common membrane defects such as pinholes, cracks, or voids. For membranes incorporating nanometer- or micrometer-sized filler materials within a continuous matrix, e.g., *mixed matrix membranes*, FIB-SEM tomography enables assessing the local concentration, three-dimensional spatial location, and orientation of the filler components (Rodenas et al. 2014). The resolution provided by XTM, in the micrometer range, permits imaging the porosity of, e.g., microfiltration membranes. The three-dimensional membrane models resulting from the reconstructed tomograms (see Fig. 2b for an illustration) can be used as the basis to simulate fluid permeation through the membrane. In the case of CSM, the sub-micrometer

spatial resolution, in combination with the selective imaging of, e.g., fluorescent species, makes it suitable to study the three-dimensional spatial distribution of biomolecules and other structures, either intrinsically fluorescent or adequately stained with a fluorescent contrast agent, within the porous structure of microfiltration. This approach has been demonstrated to investigate the process of membrane (bio-)fouling (Zator et al. 2007).

Three-Dimensional (3D) Microscopy Methods

► 3D-Imaging Methods for Membranes

Time Lag Method for Mass Transport Properties Evaluation in GS

Donald R. Paul

Department of Chemical Engineering, Texas Materials Institute, Austin, TX, USA

The diffusion time lag method is a useful way to obtain the diffusion, solubility, and permeability coefficients from a single experiment when certain conditions are satisfied. It takes advantage of the initial transient portion of a permeation experiment prior to the establishment of steady-state permeation. Considering a polymer membrane of thickness l with an initial concentration of penetrant of C_0 throughout and at time $t = 0$, the concentration of penetrant is set at C_2 within the upstream face of the membrane and C_1 at the downstream face. The accumulative amount of penetrant per unit area exiting the downstream surface of the membrane, Q_t , versus time can be obtained from a solution to Fick's second law when the diffusion coefficient is constant (independent of concentration and position in the membrane), and there are no chemical reactions or adsorption processes (Crank 1975). The result is

$$Q_t = D(C_2 - C_1)t/l + \frac{2l}{\pi^2} \sum_{n=1}^{\infty} \frac{C_2 \cos n\pi - C_1}{n^2} \{1 - \exp(-Dn^2\pi^2 t/l^2)\} + \frac{4C_0 l}{\pi^2} \sum_{m=0}^{\infty} \frac{1}{(2m+1)^2} \{1 - \exp(-D(2m+1)^2\pi^2 t/l^2)\} \quad (1)$$

Time Lag Method for Mass Transport Properties Evaluation in GS, Fig. 1 A transient permeation experiment illustrating the time lag and the steady-state region (Paul 2010) (Reproduced with permission by Elsevier (Copyright 2010))

The most common situation is when $C_1 = C_0 = 0$ for which Eq. 1 simplifies to

$$Q_1 = lC_2 \left[Dt/l^2 - 1/6 - \frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \exp(-Dn^2\pi^2 t/l^2) \right] \quad (2)$$

At long enough times, the exponential terms vanish, and Eq. 2 approaches the linear asymptotic line given by

$$Q_1 = \frac{DC_2}{l} [t - l^2/6D] \quad (3)$$

This steady-state line intercepts the time axis at $t = q$ or the “time lag” given by

$$\theta = l^2/6D \quad (4)$$

as illustrated in Fig. 1. The full solution for Q_1 , Eq. 2, becomes experimentally indistinguishable from the asymptotic line for $t^3 \gg 3q$. A common error in using this method is not allowing enough time to establish steady state.

For simple gases, the equilibrium concentration of gas in the polymer, C , for a given external

pressure p is given by Henry’s law, $C = Sp$, where S is a solubility coefficient. The permeability coefficient P can be calculated from the slope of the steady-state portion of the graph of Q_1 versus t by the definition

$$P = \frac{l}{p_2} \left(\frac{dQ_1}{dt} \right)_{ss} \quad (5)$$

where p_2 is the upstream gas pressure and when the downstream pressure is essentially zero. Since $P = DS$, it is possible to compute all three coefficients from graphs like Fig. 1 using Eqs. 4 and 5.

Since in the above case the membrane is initially “empty,” i.e., $C_0 = 0$, gas must be absorbed by the membrane to reach steady state so Eq. 4 defines what might be called the “absorption time lag,” i.e., θ^a . For the alternate case where $C_0 = C_2$, gas must be desorbed to reach steady state so there is a “desorption time lag” which is given by

$$\theta^d = -l^2/3D \quad (6)$$

Petropoulos and Roussis have defined other time lags and evaluated various relationships among them for a wide variety of complex situations (Petropoulos 1967). Barrie et al. evaluated the time lag for laminated membranes using the Laplace transforms (Barrie et al. 1963). Frisch developed a useful mathematical procedure for constructing asymptotic solutions for permeation problems, hence time lags, for more complex situations where full solutions to Fick’s second law are not feasible (Frisch 1957), e.g., when the diffusion coefficient depends on penetrant composition or position in the membrane or when chemical reactions or adsorption processes occur.

Tissue Engineering and Regenerative Medicine

► Bioartificial Organs and Tissue

Tissue Engineering, Membrane Operations of

Simona Salerno

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

Biofabrication; Biohybrid membrane systems; Regenerative medicine

The first and the most common definition of tissue engineering states that it is “an interdisciplinary field that applies the principles of engineering and life sciences toward the development of biological substitutes that restore, maintain or improve tissue function or a whole organ” (Langer and Vacanti 1993). In other words, tissue engineering combines the principle of materials and cell transplantation to develop new tissues and/or promote endogenous regeneration. Living and functional cells are implanted or “seeded” into an artificial substrate or *scaffold* able to give them specific cues and to recapitulate the *in vivo* milieu of their own microenvironments, driving and supporting three-dimensional tissue formation. With the purpose of producing functional replacement tissues for clinical use, the principles of

tissue development and growth must be understood and applied. On the other side, the supporting materials, both *ex vivo* as well as *in vivo*, are critical and crucial to engineer living tissues. They allow cell adhesion and migration, exert specific mechanical and biological influences able to modify cell shape and functional behavior, and at the same time enable the delivery and diffusion of biochemical factors, cell nutrients, and products. To achieve these purposes and the goal of tissue reconstruction, scaffolds must meet some specific requirements.

Among artificial scaffolds, polymeric membranes are notably suitable as supporting material in tissue engineering, thanks to their characteristics of stability, biocompatibility, and selective permeability. Polymeric membranes could mimic the extracellular matrix (ECM) with which cells interact, allowing the organization of cells in a three-dimensional architecture. Membranes are able to modulate the adhesion, proliferation, and differentiation of cells and the selective transport of metabolites and nutrients to cells and removal of catabolites and specific products from them (Morelli et al. 2009). Material properties and characteristics as well as surface chemistry and topography strongly impact and affect cell-material interaction and thereby cell response and tissue formation. The cell-material interaction is a complex and dynamic multistep process that mimics natural interactions of cells with their natural ECM. It consists of early events, such as adsorption of proteins from *ex vivo* cell culture media or from *in vivo* biological fluids, followed by cell adhesion, due to the recognition of the EMC components by cell receptors, and cell spreading engendered by cytoskeleton rearrangements. Successively, late events are related to migration, growth, differentiation, and functional activation of cells. Among cellular functional activities, ECM secretion and deposition by the same cells strongly contribute to the tissue growth and maturation.

Thus, the choice of membrane materials and membrane properties is crucial to engineer target tissues. A high *porosity* and an adequate *pore size* are necessary to foster both cell adhesion and

diffusion of nutrients and metabolites. *Surface properties* and *morphology* influence the adsorption of proteins and their conformational changes and therefore cell adhesion. Protein adsorption is favored on rough surfaces rather than the smooth ones. On the other hand, smooth surfaces elicit more organized ECM deposition and more homogeneous distribution of focal adhesion. *Surface physicochemical properties* such as *wettability* and *free-energy parameters* predict membrane cytocompatibility. A proper and suitable cell adhesion takes place on surfaces with a moderate hydrophilicity. Extremely hydrophilic surfaces bind too loosely the proteins that mediate cell adhesion, while otherwise, extremely hydrophobic surfaces strongly absorb proteins perturbing their natural folding with distortion of cell receptor-binding domains. Moreover, roughness, pore size, and porosity, as well as proper pore shape and distribution, influence and enhance a rearrangement of cytoskeleton proteins that trigger the extrusion of pseudopodia from cells. These latter ones work as anchorage points for the formation of focal adhesion complexes and for cell motility, favoring cell-material and cell-cell interactions. *Topographical cues*, including grooves, ridges, steps, pores, wells and nodes, drive the cell orientation and migration and influence the organization of cytoskeleton rearrangements and consequently the cell shape. Micro-topographies could influence cell differentiation and gene expression. In neuronal tissue engineering, patterned membranes promote an oriented peripheral nerve growth (Morelli et al. 2010). A pivotal role in cell response in tissue reconstruction is played furthermore by *mechanical properties* of the supporting materials. During tissue formation, mechanical stresses play in control of cell phenotypes or “fates”, such as growth, differentiation, motility, and apoptosis. Also in tissue repair, the tissue development is actively regulated by the spatial organization and by the mechanical constraints imposed on cells (Petreaca and Martins-Green 2014). In tissue engineering, the mechanical properties of materials strictly depend on the tissue that has to be reconstructed: hard tissues such as the bone

necessitate stiff matrices and soft tissues such as tendons, ligaments, skin, fibrous tissues, muscles, nerves, and blood vessels need more elastic and flexible scaffolds. Cell spreading, proliferation, and migration are enhanced on stiffer substrates than soft ones. Many kinds of cells, like neurons, chondrocytes, fibroblasts, and vascular smooth muscular cells, migrate to stiffer region if cultured on a rigidity gradient. On polymeric membranes, an enhanced tensile modulus and strength and a high porosity are able to promote capillary development by endothelial cells (Salerno et al. 2011).

Since an efficient metabolite and nutrient transport is required for the long-term maintenance of cell viability and functions, an important tissue engineering challenge is to evaluate diffusive and convective contribution to mass transport (Curcio et al. 2005). *Transport properties* and *permeability* of membranes influence tissue reconstruction and regeneration through the diffusion of nutrients and secreted soluble factors. Specie transport through a membrane takes place because of a difference in chemical potential: difference in concentration, temperature, pressure, or combination of these variables. In the absence of solutes, the hydraulic permeance is related to the fluid viscosity and to membrane properties such as thickness, pore size and porosity, pore geometry, and tortuosity. Mass transfer through membranes in a multicomponent system with solutes and solvent occurs as a result of the differences in static and osmotic transmembrane pressures. The transport of nutrients and metabolites with a low MW occurs by diffusion, whereas macromolecular species and proteins follow a convective transport. The driving forces for diffusive and convective transport are transmembrane concentration and pressure gradients, respectively. The transport of solutes through porous membranes depends not only by transmembrane gradients but also by the size and shape of solutes related to membrane pore size and thickness. Specific physicochemical solute-membrane interactions such as electrostatic, hydrophobic, or acid-base interactions can also influence the transport across membranes.

The use of biodegradable polymer for the synthesis of biodegradable membranes represents an additional key for the development of successful implantable bio-artificial constructs. *Biodegradability* is often a requisite factor since scaffolds should be absorbed by the surrounding tissues without their surgical removal. A programmed and predictable biodegradation rate has to be consistent as much as possible with the tissue formation rate: this means that while cells are fabricating their own natural matrix structure around themselves, the scaffold should be able to break down leaving the newly formed tissue.

Titania Membranes

Toshinori Tsuru

Department of Chemical Engineering, Hiroshima University, Higashi-Hiroshima, Japan

Titania membranes show excellent chemical resistance and can be used in both acidic and basic pHs, and moreover, they show interesting photocatalytic activity. Titania ultrafiltration membranes have been commercialized by several companies. At present, extensive efforts have focused on the preparation of porous membranes having small pore sizes in the NF range (1–2 nm). Since pore sizes are believed to be controlled by the sizes of the packed particles, controlling the sol size is a crucial process for membrane processing. Anderson et al. [24] prepared nano-sized TiO_2 and ZrO_2 particles (3–5 nm) by carrying out hydrolysis and condensation reactions of metal *tert*-amyloxide with a small amount of water (molar ratio of $\text{H}_2\text{O}/\text{Ti} = 3–5$) in *tert*-amyl alcohol solutions. Hydrolysis and condensation reactions of metal alkoxides are written as follows:

Since both reactions take place by nucleophilic substitution, the electronegativity and the size of alkoxy groups are important. By using a large branched alkoxy group (*tert*-amyl alkoxide), the reaction rate can be reduced, resulting in small-sized sols. An amorphous phase predominated in the xerogel dried at room temperature and fired at 300 °C, and phase transition from amorphous to anatase and from anatase to rutile occurred from 300–400 °C to 400–600 °C, respectively. Therefore, it is important to control firing temperature in order to obtain controlled pore sizes of membranes. Titania membranes which were coated on porous alumina membranes and fired at 200 °C showed approximately a 100 % rejection

Titania Membranes, Fig. 1 Molecular weight cutoff curves for TiO₂ porous membranes (solutes: sugars, 500 ppm) (Wildman et al. 1993)

of polyethylene glycol 200 (PEG200, M. W. 200), depending on operating conditions (Xu et al. 1993). Another strategy for controlling MWCOs is the appropriate choice of sol diameters, which is used at the final coating for the separation of the top layer. (Tsuru et al. 2001) successfully prepared a variety of MWCOs for TiO₂ membranes at the same firing temperature of 450 °C using sol solutions having different sizes of sol diameters, as shown in Fig. 1. M1, M2, and M3 show MWCOs approximately 500, 600, and 800, while M4 shows nearly no rejection for α -dextrin (MW 972).

On the other hand, Société des Céramiques Techniques (SCT) claimed that they had commercialized TiO₂ NF membranes having an MWCO of 1,000 (Sarrade et al. 1996) based on research work by Commissariat à l'Energie Atomique (CEA). Colloidal sols with a diameter of 15 nm, which showed an anatase phase and which were stable up to 600 °C, were coated on porous alumina supports and fired at 500 °C. Voigt et al. (Puhlfürß et al. 2000) prepared polymeric sols from a solution of Ti-isopropoxide in isopropyl alcohol by the addition of a small amount of water. NF membranes, which were prepared by coating the polymeric sols on a TiO₂ intermediate layer (pore size 5 nm, prepared by colloidal TiO₂ sols), followed by firing at 450 °C, had an MWCO of 480 and a pure water flux of 20 l/(m² h bar) and

were applied to the separation of electrolytes. Benfer et al. (2001) also developed TiO₂ NF membranes by the polymeric sol route. Tetraethyl orthotitanate was partially hydrolyzed at conditions where the molar ratio of water over the alkoxide was less than 1, followed by the addition of an acid or organic base to control the viscosity of the polymeric sol solution, i.e., the size of the polymeric network. They also prepared zirconia porous membranes by the same method. Filtration performance of TiO₂ membranes shows comparable water permeabilities to those of polymeric NF membranes.

Toluene Removal by PV on Polymeric Membranes

Lan Ying Jiang

School of Metallurgy and Environment, Central South University, Changsha, China

Synonyms

[BTEx removal by PV on polymeric membranes](#)

Toluene is one of the volatile organic compounds (VOCs) that cause serious damage to human and animal due to their toxicity (Satyanarayana et al. 2004). The other chemicals in this category include benzene, xylenes, ethylbenzene, etc. They are collectively called as BTEX, a word composed of their initial letters. Elimination of BTEX from water, therefore, is a mandatory nowadays.

These chemicals can move freely in water and air; their sequestration is relatively difficult. Air stripping and activated carbon adsorption processes are the conventional methods for removal of BTEX from water. In recent years, a new focus for separation of BTEX from wastewaters is pervaporation. Pervaporation is a membrane process that performs molecular-scale liquid/liquid separation. It is carried out by maintaining the downstream pressure lower than the saturation pressure of the liquid at that temperature. A vacuum or gas flow is used at the permeate side to achieve the lower pressure. With the dense structure of the membrane, the interaction between membrane material and penetrant is critical to the separation efficiency. The mechanism for penetrant transport through the membrane is the solution–diffusion model, which assumes instant desorption at the permeate side of the membrane. In many researches for separating benzene, toluene, ethylbenzene, and xylenes (BTEX), toluene is used as a representative chemical (Satyanarayana et al. 2004). This approach using single chemical may give a more clear insight into the mechanism of pervaporation. The concentration of VOCs in wastewater is low. Therefore, hydrophobic membranes preferentially removing organics are much more cost-effective than hydrophilic ones. Polydimethylsiloxane (PDMS), ethylene–propylene diene monomer (EPDM), and polyether block amide (PEBA) are typical hydrophobic polymers (Blume et al. 1990; Sampranpiboon et al. 2000b; Viswanathan et al. 1995). High permselectivity of these materials is attributed to its stronger affinity for BTEX than for water. Their polymer chains are dominated by nonpolar functional groups, thus moving freely and providing high free volumes in the membrane. That is the

reason for high diffusion of organics across the membrane. To improve membrane hydrophobicity, the methyl groups are replaced by long alkyl groups in the side chains (Sampranpiboon et al. 2000a). Poly(1-(trimethylsilyl)-1-propyne) (PTMSP) is found to be much more organophilic; however, both the flux and the selectivity decreased as operation proceeds (Fadeev et al. 2000). Inorganic materials have already shown good performance in alcohol recovery, but not many reports are regarding their application in BTEX removal. The reason might be that the high production cost and the reward from wastewater treatment are skewed. In order to get materials having better performance, therefore, mixed matrix materials with inorganic particle-filled hydrophobic materials are designed (Boom et al. 1998; Panek and Konieczny 2009).

Due to their poor performance in mechanical property, hydrophobic polymer-based materials are generally made into composite membranes with a porous sublayer supporting their ultrathin dense layer. The support layers for removal of toluene from water are mainly fabricated from polysulfones, polyetherimides, polyimides, polyacrylonitriles, and polyesters that have good mechanical strength and high resistance toward the swelling of organics (Peng et al. 2003).

As mentioned above, activated carbon adsorption is a more widely used technology. But it has disadvantages such as requirement to alternating recovery steps. Also, the operational costs in air stripping are high due to the necessity to posttreatment stages for preventing water pollution into the air pollution. Likewise, pervaporation has its drawbacks. It is practical for pervaporation to recover highly dilute organic compounds in water (i.e., <10 ppm), as a result of the exponential increase of membrane area needed to yield economical productivity. Nevertheless, adsorption and air stripping are well suited to even lower concentrations. Therefore, any process design should attempt to consolidate the advantages of each technology while overcoming their individual limitations, so that separation targets otherwise unrealistic can be achieved.

- (Kocherginsky et al. 2007). At the feed-membrane surface, the component having physical or chemical affinity with the liquid or the chemicals inside the liquid (e.g., carrier) will be selectively sorbed and diffuse across the membrane. At the other surface of the membrane, the component is released from the liquid as a result stripping by the permeate fluid. Liquid membranes (LM) are broadly classified into three types: bulk, emulsion, and supported liquid membranes (SLM). In SLM, liquid for selective transport is imbedded inside the porous part of a solid (e.g., polymer) support and is kept there by capillary forces. Pervaporation (PV) through SLM applies vacuum or gas flush at the permeate side of a SLM to facilitate desorption of the organics from LM.

A new type of a hollow fiber contained liquid membrane (HFCLM) PV system was employed to separate some toxic VOCs such as trichloroethylene and toluene from water (Yang et al. 1995). In this design the highly selective organic LM is contained in the shell side between two sets of hollow fibers packed in a shell-and-tube heat exchanger arrangement. Wastewater is fed into one set of hollow fibers and vacuum is applied in the other set of hollow fibers. The separation factors and solute recoveries for the HFCLM system were higher and water fluxes lower than in a conventional pervaporation system based on silicone rubber with vacuum applied outside the silicone rubber hollow fibers. The effluent concentration data for the HFCLM were satisfactorily correlated with a material balance where the mass flux was expressed in terms of an overall mass transfer coefficient based on resistances-in-series model.

PV through SLM is a unit process involving extraction and stripping steps simultaneously. The benefits of using an LM in pervaporation are the high selectivity and specific molecular recognition achieved with the liquid and carriers possibly contained, which will reduce the energy required for the BTEX recovery. However, there are very few investigations on PV using SLM (Qin et al. 2002). The reasons can be attributed to the

Toluene Removal by PV Supported Liquid Membranes

Liquid membrane (LM) uses a thin layer of liquid as the media to preferentially transport specific component from one side to the other

well-known problem of instability of SLMs in applications. The SLM might not provide a stable organic flux, arising from the possible dissolution of LM into water phase. Further, the solid support is significantly swollen by the liquid it contains inside to such a degree that the mass transfer through it is not negligible. Consequently, the support will also influence the selectivity of the SLM.

Introduction

In the fast developing technologies era, nanotechnology is the one significant technology that has already taken a big leap. It appears to be all set for bringing in revolution in the development and advancement of techniques involved in the synthesis and fabrication of sensors and devices with great potential. The conventional microelectronics fabrication techniques are facing very harsh competitions from low dimensional strategies helping “Moore’s Law” survive and bringing down the high costs. The conventional techniques for fabrication of very low dimensional wires – say quantum wires – include wet chemistry, electron beam lithography, focused ion beam techniques, and atomic-beam lithography (Huixin). That has shown the ways for adopting newer alternative approaches which are relatively inexpensive, easier to handle, and synergistically adorned with high efficacy. Nanotechnology is one of the fastest growing new areas in science and engineering and deals with science and technology associated with dimensions in the range of 0.1–100 nm. The subject arises from the convergence of electronics, physics, chemistry, biology, and materials science to create new functional systems of nanoscale dimensions. The ability to fabricate structures with nanometric precision is of fundamental importance to any exploitation of nanotechnology. Nanotechnology is predicted to have a major impact on the manufacturing technology in the next few decades from now.

It is now well known that size of the devices and components dictate many unusual traits and characteristics where quantum effects become more predominant. In the recent years, there has been a tremendous spurt in the potential applications of metallic as well as nonmetallic nano-/microstructures and materials. Quasi-one-dimensional nanostructures and materials like nanowires, fibers, tubules, etc., having high aspect ratio, would provide unusual and uncommon properties like strength and hardness enhancement, dramatic changes in electrical conduction, field-ion-emission through tunneling phenomenon, optical, magnetic, and chemical, and other important functional attributes which are found to

be enhanced when the size reduction comes into play. Materials with nanoscopic dimensions may exhibit quantized conductance (Landauer 1989) which not only has potential technological applications in various areas but also is of fundamental interest.

It has been approximately five decades since researchers first began exposing materials like polymers to ionizing radiation and reporting the occurrence of cross-linking and other useful effects. Today, a substantial commercial industry is in place based on processing of polymers with radiation. Innovation in this field has by no means ended; important new products made possible through radiation technology continue to enter the marketplace, and exciting new innovations in the application of radiation to macromolecular materials are under exploration at research institutions around the world.

This entry reviews the technique – the “template synthesis” (TS) – involving the porous membranes (specific reference is made to track-etch membranes) which are spin-off from the radiation-matter interaction and are used as tools in the development of nano/micromaterials, structures, and devices. The recent past has witnessed the keen interest being generated on the use of innovative technologies like TS in the production of nanomaterials’ fabrication involving materials like metals, nonmetals like semiconductors, magnetic multilayered nanowires, conducting polymers, glasses, nanotubules, wires, whiskers, etc., reported from various authors and from our lab (See refs in (Chakarvarti and Vetter 1998; Martin 1996; Brumlik et al. 1994; Chakarvarti and Vetter 1993; Kumar et al. 2004a, b, c, d, e, f; Sekhon et al. 2004; Kumar et al. 2005; Chakarvarti et al. 2005a; Kumar and Chakarvarti 2005; Chaudhri et al. 2006a; Singh and Chakarvarti 2008a; Chakarvarti 2007a; Kumar and Chakarvarti 2007a; Chakarvarti 2007b; Kumar et al. 2007a, b; Chaudhri and Chakarvarti 2008a; Kumar et al. 2008a)).

Nano Synthesis Approaches

All the conventional and available nanosynthesis techniques can be categorized into two complementary approaches:

- The top-down approach – starting with the bulk material and carving the way down to the nanoscale, and
- The bottom-up approach – starting at the molecular level and fabricating up the material through the small cluster level to the nanoparticle and the assembly of nanoparticles.

Nanotechnology provides the ability to fabricate structures with nanometric precision that is of fundamental importance. The potential of combining radiation effects with nanomaterials has been recognized from the very early stages of nanoscience research. In the many uses of nanostructures, and nanoparticles in particular, from catalysis, bio-sensing, nano-electronics, magnetic applications including separations, mechano-chemical conversion, and to molecular computing radiation can play a significant role.

Many nanostructured systems, like metal sulfide semiconductors of nanometric matrices, PC-controlled biochips for programmed release systems, nano-ordered hydrogels based on natural polymers, development of polysaccharides, emerge out from the use of radiation (UV beam, electron beam, or focused ion beam) techniques which offer unmatched reproducibility and very narrow size distribution. The relative advantages and deficiencies of each of them are still to be clarified as the technology advances. However, whether UV or electron beam will lead to the highest resolution is still debated.

The studies on natural rubber-clay composites and thermoplastic natural rubber-clay composites have given interesting results. Nanomaterials with high abrasion and high scratch resistance will find industrial application.

The formation of microporous and nanoporous membranes having highly uniform geometry and precisely determined structures is an exciting example of industrial application of ionizing radiation. These materials, called track-etch membranes (TEMs) were first made by irradiation of polymeric sheets, micas, and glasses with fragments from the fission of heavy nuclei such as californium or uranium (nuclear track-etch method). This technique presents a great limitation due to contamination of the foil with

radioactive products so that “cooling” of the irradiated material, before using, is needed; this usually takes a few months. The second method makes use of heavy ion beams, usually of energy on the order of several MeV, from accelerators and presents quite a few advantages over the former one which are: (a) no induced radioactivity in the irradiated material when ion energy is below the Coulomb barrier; (b) all tracks show the same etching properties; (c) deeper penetration in the material owing to higher energy of particles; (d) higher density (even $>10^9 \text{ cm}^{-2}$ for smaller pores) track arrays; and (e) easier control of the impact angle and production of arrays of parallel tracks. A heavy ion beam with acceleration energy of more than 1 MeV/n deposits its energy to a substrate in a region $<10 \text{ nm}$ in diameter (an ion track); the depth of the affected region can be regulated by changing the energy or replacing species of ion particles. Widely used polymers for ion track membranes are polyethylene terephthalate (PET) and polycarbonate (PC). By bombarding PET or PC films with swift heavy ions (e.g., Ar^+ , N^+ , or Xe^+) latent radiation damage linear tracks are created through the samples.

According to the following sensitization and etching with an alkali solution (NaOH for instance), uniform cylindrical, conical, tunnel-like, or cigar-like pores have been obtained. Pore sizes or dimensions depend upon various factors, viz., the nature and energy of incident particles, the target material, etch conditions, e.g., temperature, nature of etchant, pre-etch storage conditions, etc., and are controllable.

Cylindrical channel 0.02–5.0 μm in diameter with lengths of 10–50 μm , membranes containing anywhere from a single pore up to $10^9 \text{ pores/cm}^{-2}$ have been produced, and thin film polymer membranes having highly uniform pore size and a wide variety of porosities in well-distributed areas of the template (patterning) are already commercially available. A number of modification methods have been devised for creating TEMs with special properties and functions.

These isoporous membranes are used as template materials for the synthesis of micro- and nanostructures. The template-base method consists of filling a host porous medium with one or

more desired materials. Three main processes are used for the synthesis of various combinations of polymers and/or metals:

- (a) electrodeposition, where one side of the template coated with a metallic layer, or the template support itself, is used as a cathode for electroplating; (b) chemical polymerization where a solution of the desired monomer and initiator, in which the template membrane is dipped, is left to diffuse through the pores of the templates leading to a polymerization reaction in these pores; (c) electroless plating where a catalyst to the pore walls is applied which facilitates the deposition of metal on the activated pores of the template. The micro- or nanomaterials, which are produced in this way, take the form of wires or tubules. Magnetic, conducting, and superconducting nanowires and nanotubules in array or isolated mode possessing special properties have been manufactured in this way.

There are two distinct nano-fabrication processes using heavy ion beams; one is nano-hole formation due to the damage of ion beam path, and the other is nanowire formation due to cross-linking of polysilane, which is also caused by heavy ion beams. Potential applications in devices such as microwave filters for shielding microwave ovens and mobile phones, or in chemical detectors and biosensors with conductive polymer nanotubules are also being seriously considered.

The fabrication of ion track membranes made of PET has been reported to develop selective membranes for the separation of toxic metal ions, biomolecules, and biological cells because of the advantages to control the pore size and the properties of the internal surfaces of the pores.

Methodology

Track-Etch Membranes (TEMs)

The most widely used materials in manufacturing TEMs are polymers, micas, and rarely this glass sheets. TEMs, also known as nuclear track filters (NTFs), have emerged as spin-off from solid state

nuclear track detectors (SSNTDs) – solid dielectric materials capable of storing damage trails of energetic heavily ionizing ions which can subsequently be chemically amplified for observation as pores either through, say SEM or optical microscope. The art and science used in crafting of TEMs as templates involves two steps – irradiation of an SSNTD foil or a film by heavy energetic ion beam creating damage trails, also called as latent tracks and, followed by a controlled chemical etching of these latent tracks so as to produce see-through pores in the host material. The size and dimensions of the etched pores can be controlled conveniently through parametric control over the nature and energy of the intruding ions, the host material as target to be developed as template, chemical etch conditions, viz., nature, concentration, temperature, agitation, etc., besides preirradiation and postirradiation storage conditions of the target material. The etched pores can have diameter ranging from few nm to mm. NTFs have been put to numerous other applications besides their use as templates. There exists a wealth of literature on SSNTDs and related topics. As discussed already, a large number of materials are used in manufacturing of NTFs which include mainly polymeric sheets, micas, glasses, etc. The particle track-etch technique, therefore, enables the generation of definite shaped pores which can either be used individually in the form of single particle track or collectively in the form of pore arrays constituting many pores – distributed either stochastically (pore density as high as $10^{10}/\text{cm}^2$), or in a well-defined spatial geometry through the control of the drilling particle beam used in “write mode.” Areal dispersion usually lies between 2 % and 20 % and a 10 MeV/nucleon heavy ion (say, for example, various projectiles used are collimated beam of fission fragments, heavy energetic ions like U, Pb, Ag, Si, Bi, etc., whose range in the target material is far greater than the thickness of the target) has a range of the order of 10 μm in many polymers (Williams and Giordano 1984). The custom made NTFs are available in a wide variety of pore size and porosities. The crafting of TEM templates through ions has been discussed in details (see for example, (Possin 1970; Williams and

Giordano 1984; Klien et al. 1993); etc.). Handled adequately and properly, these TEMs can enable wires, tubules, solid cylinders, conical or tapered needles, etc., with a well-controlled dimension and shape besides a large aspect ratio. The dimensional parameters can vary from 10 nm to several micrometers with aspect ratio as high as 10–1000. The pores can be “drilled” with alignment in any direction depending upon the angle of incidence of the beam with the target. The synthesized members may either be left within the pores as embedded or can be removed either by dissolving or removing the host or pulling out mechanically but carefully of the host matrix. Figure 1 shows

Template Synthesis: A Technique

The template approach has been extensively investigated in the synthesis of various nanostructures. For example, mesoporous oxides with well defined and ordered porous structure can be readily synthesized using surfactant or copolymer micelles as templates through sol-gel processing. However, template-based synthesis is most commonly and widely used to prepare free standing, nonoriented and oriented nanowires, or nanorods or nanotubes; the latter is also referred to as nanorod or nanowire or nanotube arrays. The most commonly used and commercially available templates are anodized alumina membrane (AAM) and radiation track-etched polycarbonate (PC) membranes. Other membranes have also been used, such as nanochannel array on glass, radiation track-etched mica, mesoporous materials, porous silicon by electrochemical etching of silicon wafer, zeolites (Ozin 1992), and carbon nanotubes. Bio-templates are also explored for the growth of nanowires and nanotubes such as Cu, Ni, Co, and Au nanowires. The commonly used alumina membranes with uniform and parallel pores are made by anodic oxidation of aluminum sheet in solutions of sulfuric, oxalic, or

phosphoric acids. The pores can be arranged in a regular hexagonal array, and densities as high as 10^{11} pores/cm² can be achieved. Pore size ranging from 10 nm to 100 μ m can be made. PC membranes are made by bombarding a nonporous polycarbonate sheet, typically 6–20 μ m in thickness, with nuclear fission fragments to create damage tracks and then chemically etching these tracks into pores. In these radiation track-etched membranes, pores have a uniform size as small as 10 nm, but they are randomly distributed. Pore densities can be as high as 10^9 pores/cm². In addition to the desired pore or channel size, morphology, size distribution and density of pores, and template materials must meet certain requirements. First, the template materials must be compatible with the processing conditions. For example, an electrical insulator is required for a template to be used in electrochemical deposition. Except for the template-directed synthesis, template materials should be chemically and thermally inert during the synthesis and following processing steps. Secondly, depositing materials or solution must wet the internal pore walls. Thirdly, for the synthesis of nanorods or nanowires, the deposition should start from the bottom or one end of the template channels and proceed from one side to another. However, for the growth of nanotubules, the deposition should start from the pore wall and proceed inwardly. Inward growth may result in the pore blockage, so that should be avoided in the growth of “solid” nanorods or nanowires. Kinetically, enough surface relaxation permits maximal packing density, so a diffusion-limited process is preferred. Other considerations include the easiness of release of nanowires or nanorods from the templates and of handling during the experiments. AAM and PC membranes are most commonly used for the synthesis of nanorod or nanowire arrays. Both the templates are very convenient to use during the growth of nanorods by various growth mechanisms, but each type of template also offers a few disadvantages. The advantage of using PC as the template is its easy handling and easy removal by means of pyrolysis at elevated temperatures, but the flexibility of PC is more prone to distortion during the heating process, and the

removal of the template would occur before complete densification of the nanorods. These factors would result in broken and deformed nanorods. The advantage of using AAM as the template is its rigidity and resistance to high temperatures, allowing for the nanorods to densify completely before removal. This would result in a larger surface area of fairly free-standing and unidirectionally aligned nanorod arrays. The problem with AAM is the complete removal of the template after nanorod growth, which has so far been unsuccessful using wet-chemical etching.

The technique of TS (Ozin 1992) may be classified into three categories depending upon the mode of use of templates (Huixin): the negative template method, positive template method, and surface step-edge template method. The negative template method which is the most popular and widely used techniques of TS allows the use of prefabricated nanopores in solid templates, and the material is deposited into these pores normally using electrochemical techniques. After removing (say by way of dissolving) the host template, free-standing elements as wires, cylinders, or conical structures can be obtained. The method has been regarded as “brute-force” method as the synthesized ensemble structure depicts the true replication of the morphology of the pores (Foss 2002). The fabrication of such templates involves many techniques including heavy ion irradiation of solid insulating materials like polymeric foils, micas, glasses, etc., producing so-called TEMs. More details would follow later. The positive template methods use wire-like substrates like DNA (size ca. 2 nm) (Braun et al. 1998), carbon nanotubes (Fullam et al. 2000), etc., on the outer surface of which the material is deposited to the desired dimensions. The removal of templates can produce wire-like or tube-like structures. Other positive templates have been discussed by Huixin He and Nongjian J. Tao (Huixin). The surface step-edge templates, also known as “step-edges decoration,” use the fact that there is preferential or selective deposition of many materials initiating on the defect sites. Zach et al. (Zach et al. 2000) and Bera et al. (Bera et al. 2004) used this technique for generating conductive metal oxide (MoO_x) at the step-edges of HOPG, which after reduction in

appropriate environment could yield metallic Mo nanowires.

When electrodeposition is carried out, the nucleation of nanostructures on the electrode substrate via template pores during electrodeposition is influenced by the crystal structure of the substrate, specific free energy, and other factors like adhesion energy; orientation of the lattice of the substrate; etc., and the final size distribution of electrodeposits is strongly dependent upon the growth and nucleation kinetics (Bera et al. 2004). Template-assisted electrodeposition process can be divided into two categories: active template-assisted process which results from growth of nuclei that essentially nucleate at the pores and defects of the substrate, while the other is known as restrictive template-based electrodeposition used mostly in the synthesis of metallic nanowires, involves deposition of metal into the prefabricated and designed pores within an inert, insulator membrane or template. PTM, porous alumina, conductive polymers, carbon, etc., have been used as templates which fall under this category (Bera et al. 2004).

Negative Template Synthesis

The basic and underlying principle of negative TS is similar to that of producing materials through the use of replication, e.g., die-casting or molding like making ice candies. There are many methods used in practice for preparing nanomaterials right from milling to lithographic techniques (Hhadjipanayis and Siegle 1994). These techniques suffer from the problems like little control over the final morphology of the resulting nanoproductions, ensembles, and materials. The TS has in turn edge in this regard. It enables the synthesis of a variety of materials ranging from micro- to nanodimensions, high aspect ratio, and of desired morphology and geometry – the single unique attribute which makes this route as most acceptable and economical too. A template, in a general sense, may be defined as a predesigned structure within which a network exists, which can be utilized for further use. Thus, for example, a membrane with prefabricated cavities or pores of known morphology, number, distribution, and configuration may also act as a template; the pores

of which can facilitate replication by any suitable means. Removal of the host template would lead to the presentation of ensembles whose morphological and stereo-chemical features and traits might replicate the original cavities or pores in the template. Here in this technique, materials can be deposited within the cavities or pores or any other dimensional structures, by various methods like electrochemical or chemical reduction (electroless) of the appropriate ion. Depending upon the template geometries and the controlling factors, functional procedure, and related parameters, the generated structures can be monodisperse homogeneous or heterogeneous, multilayered, short, squat fibrils, long needles, hollow tubules, tapered conical (single or double cones) elements, etc., depending upon the template factors stated above. The interesting aspect is that one can have complete control over the aspect ratio (length and diameter ratio). Metallic as well as nonmetallic tubules can be obtained by chemically derivating the pore/cavity walls by providing molecular anchors so that the electrodeposited metal deposits preferentially on the walls layer by layer, leading to hollow tubules when the process is terminated at a preestimated time interval (Martin et al. 1990). The synthesized structures can remain either inside the host structures in the templates or they can be rendered free, and collected as ensemble. Alternatively, an ensemble of nano-/microstructures that protrude from a surface like the bristles of a brush can be produced. The technique is blessed with simplicity and nano-/microstructures with extraordinary low dimensions have been reported to be produced (see refs in Parthasarthy et al. 1995; Schonenberger et al. 1997; Sima et al. 2004) which are otherwise difficult to manufacture using lithographic methods.

History and Development of Negative Template Synthesis

Bean (Bean 1969) first demonstrated the art of filling the pores of a membrane with silver followed by Possin (Possin 1970) who utilized electrodeposition technique in the fabrication of thin wires as small as 400 Å using mica with etched pores as templates for synthesis of such

elements of the nanostructures. Williams and Giordano (Williams and Giordano 1984) claimed to have reduced the size down to 80 Å after effecting some refinements to the technique. Penner and Martin (Penner and Martin 1987) reported on the generation and characterization of ultra-microelectrodes with radii as small as 1000 Å. Klien et al. (Klien et al. 1993) reported on the fabrication of graded CdSe/CdTe heterostructures and development of chemistry for fabricating II-VI chalcogenide semiconductors CdSe and CdTe within the template membranes producing micro-diode arrays consisting of micro-cylinders retinal rod cells – the photoreceptors in the human eye – and having ca. five times smaller diameter than that of photoreceptors. Team led by Prof. Charles Martin at Colorado State University, USA, has been actively engaged in exploring and exploiting the TS for its full potential and a large number of reports are available (see refs in (Huczko 2000)). Researchers at GSI at Darmstadt, Germany (where this author has had also his first hands-on experience with the technique of TS for a short duration during early 1990s), have also many reports to their credit for developing the technique further and generating nano-/microstructures (see, for example, ref. (Spohr 1990)). A large bulk of literature since then has been published on the negative TS and its applications (see refs in (Chakarvarti and Vetter 1998; Huczko 2000; Martin 1994)). This lab has also been reporting from time to time on the synthesis of nano-/microstructures, devices, and tubules using TEMs as templates (see refs. (Chakarvarti and Vetter 1998; Martin 1996; Brumlik et al. 1994; Chakarvarti and Vetter 1993; Kumar et al. 2004a, b, c, d, e, f; Sekhon et al. 2004; Kumar et al. 2005; Chakarvarti et al. 2005a; Kumar and Chakarvarti 2005; Chaudhri et al. 2006a)). Almost simultaneously, the TS also included porous alumina (Al_2O_3) membranes, which are prepared electrochemically from aluminum (the fabrication method of anodic porous alumina started as early as 1950s), and have usually high pore density (as high as $10^{11}/\text{cm}^2$) with pores as small as ca. 5 nm, arranged in hexagonal arrays (Despic and Parkhutik 1989).

Here in the present review, detailed discussion has further been carried only on negative template synthesis using TEMs as templates for synthesis of nano-/micromaterials.

Materials

While sieving properties of porous membranes have been used from as early as some thousands of years, but it is relatively only recently that a technological application like TS of nano-/microstructures has been brought to this process – almost a by-product having no relation with sieving properties. Until recently where the use of positive template synthesis has started, most of the work had been carried out using negative template synthesis involving mainly two types of membranes: TEMs and porous alumina (Al_2O_3). Others include nanochannel array glasses, zeolites, proteins, etc. A wide variety of other nanoporous solids that can be used as templates are cited elsewhere (see, for example, ref. Martin 1994).

Template Synthesis of Low Dimensional Structures and Devices

The strategy for embedding matter of interest within the etched pores or channels in the template is the material's placement through some suitable mechanism at the desired places, viz., pores. This can be accomplished in four ways. (Huixin) Using the capillary action of the pores/channels and enabling the solution of the dissolved material entering into the pores, followed by slow evaporation of the solvent. This will lead to growth of supersaturated structural elements (Landauer 1989) using electrochemical (galvanic) technique which is widely practiced. Here, electrodeposition of the desired metal ions is carried out either using two-electrode or three-electrodes electroplating cell (Bera et al. 2004; Chakarvarti and Vetter 1998) using electroless (nongalvanic) deposition technique (Linkot et al. 1999) and references therein (Bercu et al. 2004). The underlying principle is to create nucleation centers on the pore walls and then precipitate the desired material on these nucleation centers. Through controlled

manipulations, one can synthesize hollow as well as solid tubules. Metals like Cu, Ni, Au, etc. or chalcogenides are dissolved in suitable solvents and precipitation can be facilitated on the pore walls. Martin (1996) using chemical reactions, say, by permitting two reagents meet within the pores and react, produced precipitates, followed by drying process and their retrieval (Kumar et al. 2004d). The necessary prerequisite is that the penetrants acting as reactants must be hydrophilic otherwise one would require to apply hydrostatic pressure to forcibly inject them into the pores. In case of two gases (or one as gas and other participant as liquid) as reactants entering from both the faces of the template, the reaction can be accomplished within the pores. For more details, see references in Ferain and Legras (2003).

In the proceeding paragraphs, more details of galvanic synthesis only are being provided. As mentioned, the technique is based upon the earlier work of Bean (Bean 1969), Possin (Possin 1970), Spohr (1982), Williams and Giordano (Williams and Giordano 1984) and, Penner and Martin (1987). The simple underlying concept of electro-deposition of metals through electroplating is described as an electrochemical process in which metallic ions in supporting solution are reduced to the metallic state at the cathode, which, if closely covered by an NTF as a template and as an overlay, would lead to the formation of growth of plated film as the embodiment of micro- or nano-structure. The pores of the NTF used would act as template (see Fig. 1).

Electrochemical Cells and Electrodeposition

A scientific treatment of galvanic process is in fact complicated, and development of optimum plating conditions may be obtained through one's personal experience obtained through repeated trials under the given inputs. The age and condition of electrolyte, viz., temperature, pH, concentration, agitation rate, purity of solvent as well as electrolyte solute, additives and their amount, uneven current distribution, increase of specific resistivity of electrolyte, formation of gas bubbles and gas blankets at electrodes excessive inter electrode distance, etc. affect the quality of

Track-Etch Membranes as Tools for Template Synthesis of Nano-/Microstructures and Devices, Fig. 3 Copper microstructures (Chakarvarti and Vetter 1998)

Track-Etch Membranes as Tools for Template Synthesis of Nano-/Microstructures and Devices, Fig. 4 Silver conical microstructures (Kumar and Chakarvarti 2005)

deposition. Plating in small crevices or pores is very difficult. The solutions should have good micro-throwing powers – the ability of a solution to plate into fine cavities or defects on the surface such as pores, pits, polishing lines, and scratches – besides the good covering power, the ability of an electrolyte to deposit metals into pores where current density is low. Copper, for example, has poor macro-throwing power but can possess excellent micro-throwing power. Electrodeposition of metals such as those which are more electronegative (e.g., aluminum, molybdenum, tungsten, titanium, tantalum, zirconium, niobium, etc.) is not always possible from aqueous solutions. Electrodeposition on metals in corrosive electrolytes or galvanic deposition of noble metals such as gold and silver on base metals like copper needs much care as the adhesion of the plated mass is found to be poor. With microporous membranes, rinsing off the membranes with 3 % H_2SO_4 followed by distilled water and absolute ethyl alcohol would facilitate the galvanic process in the case of metals like zinc, indium, etc. (Possin 1970). Presoaking of the cleaned and washed template with the given electrolyte is also helpful (Chakarvarti and Vetter 1991). Many detailed studies of the electrochemical fabrication process for nanostructures have been reported by many workers (Schonenberger et al. 1997; Whitney et al. 1993).

Track-Etch Membranes as Tools for Template Synthesis of Nano-/Microstructures and Devices, Fig. 5 Buds and caps as over-deposition

For electrodeposition of metals, some special types of electroplating cells are used (Penner and Martin 1987; Chakarvarti and Vetter 1991; Dobrev et al. 1994) which offer a low ohmic voltage drop across the electrodes even when the cell is filled with a poorly conducting electrolyte. There are various cell designs available: two electrodes and three electrode cells. The cell designed by Dobrev et al. (1994) has the provision for mechanical stirring besides a thermostat for maintaining the desired temperature of the water contained in a jacket surrounding the cell as constant.

Electrodeposition is accomplished by simply coating one face of the overlaid template with a metal film (preferably gold) to serve as a working electrode on which electrodeposition takes place. The thickness of the film is appreciably large if the pores in the templates have also larger size. Alternatively, a metallic tape with conducting adhesive on the surface may also be used for fixing up the template membrane while the pores on the other face act as channel templates with one end sealed (Chakarvarti and Vetter 1991). In order to make

Track-Etch Membranes as Tools for Template Synthesis of Nano-/Microstructures and Devices, Fig. 6 Copper hollow tubules

the pore walls conducting so as to be conducive in convenient electrodeposition by way of providing molecular anchors, the template may be moistened with solution like chloroplatinic acid (Penner and Martin 1987) before electrodeposition is carried out. The use of electroless plating on the pore walls of polymeric templates might also be useful before galvanic process is started. This needs etching of polymer surfaces with chromic-sulfuric acid solutions followed by activation by immersion in tin and palladium solutions, or a colloidal solution containing these ions. This process is called “conditioning” which is required to improve the wettability of the polymer surface, which further facilitates adhesion of the plated metal. During electrodeposition of the metal at the cathode, the depletion of the metal ions increases the absolute value of the deposition potential and if this exceeds the hydrogen overvoltage for the given process, hydrogen also deposits resulting into a loss of plating efficiency and increase in pH of the electrodeposited metal, ultimately causing “burning” of the thin deposition. In order to avoid the development of overpotential, factors like increase in bath temperature and the agitation or the electrolyte are helpful. For applying deposition potential and monitoring the current and potential drop across the cell, a good constant voltage (potentiostat) power supply is

needed. It is found that while DC electrodeposition can produce good quality nanowires, the filling of the pores is partial ca. 10–20 % (Chakarvarti and Vetter 1991). A high filling

ratio as well as generation of uniform array of structures can be achieved by using AC electrodeposition. Various AC pulse shapes like saw-tooth waves, triangular, sine waves, but not

square wave (square wave potential pulses may be used for obtaining multilayered nanowires, see reference Piroux et al. (1994)) with varying frequencies have been used for better results, increased crystallinity and homogeneity (Yin et al. 2001). Nielsch et al. (2000) used pulsed electrodeposition method and demonstrated that it suits for uniform deposition of porous alumina with almost 100 % (Nielsch et al. 2000). From our experience, we have found that initial high voltage for short duration followed by low values (the

process is called “striking”) produces good results. Chakarvarti and Vetter (Chakarvarti and Vetter 1998) have suggested a formula in order to calculate an approximate optimum current for satisfactory results. It is of interest to note that the template synthesized materials (metals as well as semiconductors) in the form of solid cylinders, wires, or whiskers can be crystalline (Dobrev et al. 1994; Chakarvarti et al. 1996).

Synthesized Structures and Devices: Some Results
Some of the metallic, nonmetallic homogeneous and heterogeneous structures and devices synthesized in this lab are shown in the Figs. 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, and 14. The template used in all cases were TEMs of Makrofol polycarbonate having pores with different shapes (some cylindrical and others conical). The Makrofol foils were got irradiated at Gesellschaft für Schwerionenforschung (GSI), Darmstadt, Germany. Also some polycarbonate foils were obtained from Whatman. More details and descriptions can be found from the references quoted.

Some of the nano-/microdevices synthesized were resonant tunneling diodes (RTDs) made from heterojunctions of metal-semiconductors

(Cu-Se, Zn-Se, Cd-Te systems, see refs. (Kumar et al. 2005, 2008a)) besides field-ion emitters (Kumar et al. 2004g, 2007b) using metallic nano/micro-tipped cylinders of copper and silver. For filling up the template pores, the electrodeposition was carried out from one face and the process was interrupted when the pores were filled half-way through. The electrolyte was replaced by another one with different metal/semiconductor material composition, and the deposition was further carried out till the pores are filled up to the brim. Figure 15 shows typical I–V characteristics of nano-RTDs synthesized from Zn-Se deposition in Makrofol PTEMs, confirming the fact that nature manifests identical both in small scale and macro scale as well. Figure 14 shows a floral display as a by-product of template synthesis process.

More results on the effect of size as well as temperature of the synthesized RTDs of II–VI materials, modeling of RTDs, and other aspects of template synthesis of variety of materials have been reported (Kumar et al. 2005, 2007a, b, c, 2008a, b, c, d, 2009, 2010a, b, 2011a, b, c, d, 2012a, b, c, d, e, 2013; Chakarvarti 2007a; Kumar and Chakarvarti 2006, 2007a, b, c, d, 2010, 2012; Chaudhri et al. 2006b, 2010;

Traditional Diafiltration

Zoltán Kovács

Department of Food Engineering, Institute of Bioengineering and Process Engineering, Szent Istvan University, Budapest, Hungary

Traditional diafiltration (TD) is the most common type of batch diafiltration technique that accomplishes the selective separation of a macrosolute-microsolute mixture as well as the concentration of macrosolute by employing a constant-volume dilution mode step that is preceded and/or followed by concentration mode operational steps.

Due to its straightforward concept and simple configuration, TD is the most frequently used batch diafiltration technique employed in various pressure-driven membrane filtration systems including reverse osmosis, nanofiltration, ultrafiltration, and microfiltration applications. TD process normally consists of three consecutive operational steps in the following order:

1. Pre-concentration step, to increase the concentration of macrosolute up to an intermediate level
2. Constant-volume dilution step, to “wash out” microsolute by a diluant introduced into the system in order to improve the recovery of the material in the permeate or to improve the purity of the retained phase
3. Post-concentration step, to further reduce the volume and to concentrate macrosolute to the final, desired level

In certain cases, if optimality requires, the three-step TD is reduced to a two-step process with either (1) or (2) omitted from the sequence. Note that filtration in *concentration mode* removes some of the microsolute but does not reduce its concentration in the feed tank. Even in case of freely permeable microsolute (i.e.,

rejection is equal to zero), the microsolute concentration remains constant in the feed tank. Thus, concentration mode is to be coupled with constant-volume dilution mode to achieve a high level of macrosolute-microsolute separation.

The generalized process model for both concentration mode and dilution mode can be written as

$$\begin{aligned}\frac{dc_i}{dt} &= \frac{c_i q}{V} (R_i - \alpha), & c_i(0) &= c_{i0}, \\ \frac{dV}{dt} &= (\alpha - 1)q, & V(0) &= V_0\end{aligned}$$

where c_i is the solute concentration in the feed tank, R_i stands for the rejection of component i , V represents the volume in the feed tank, and α is the proportionality factor defined as the ratio of diluant flow to permeate flow q . By definition, in concentration mode, $\alpha = 0$ (i.e., no diluant is added), while in constant-volume dilution mode, $\alpha = 1$. V_0 and c_{i0} denote respectively the initial feed volume and the initial feed concentration of the solute i . This initial value problem describes the evolution in time of the feed volume and the feed concentration of any solute under the assumption that the diluant is free of component i , and the feed tank is well mixed. Note that the time-dependent variables (i.e., permeate flux and the solute rejections) are, in a general case, a function of feed concentrations and may vary with operation conditions (temperature, pressure, cross-flow velocity, etc.).

Assuming constant rejections and flux, the differential equations can be reduced to simple algebraic equations. The resulting exact solutions are:

- For concentration mode, the actual concentration of component i at any time instant gives $c_i = c_{i0} n^{R_i}$ where n is the volume concentration factor defined as the ratio of initial feed volume to actual feed volume.
- And for constant-volume dilution mode, it holds: $c_i = c_{i0} e^{D(R_i - 1)}$ where D is the dilution factor given as the ratio of applied diluant volume to feed volume.

The subject of optimization procedures is a TD process that aims at increasing the macrosolute concentration from c_{10} to c_{1f} and reducing the microsolute concentration from c_{20} to c_{2f} (e.g., Beaton and Klinkowski 1983; Dutré and Trägårdh 1994; Foley 1999; Wang et al. 2007; Paulen et al. 2012). TD is characterized with a sequence $\alpha(t) = \{0, 1, 0\}$ with two unknown switching times at the end of the first and of the second process steps. In engineering practice, process optimization is usually aimed at finding optimum values for n and D . Note that it poses a mathematically analogous problem to finding switching times. The problem of determining optimum switching times for a given technological objective has been the subject of many optimization studies, most of them considering process models with constant (i.e., concentration-independent) flux and rejections and a few dealing with concentration-dependent membrane response models (e.g., Bowen and Mohammad (1998); Kovács et al. 2008). The simplifying assumptions, when their appropriateness is not carefully checked for the given separation process, can easily result in suboptimal process control.

Optimization procedures may consider different objective functions, such as minimization of operational time, diluant consumption, or a complex economic index. This latter involves the costs of utilized diluant and pump operation and incorporates macrosolute loss-related costs. The optimal solution is case specific varying with the complexity of the permeation model (i.e., rejection and flux behavior), the initial and final values, and the constraints involved in the model.

Transient Membrane Transport, Analysis of

Zbigniew J. Grzywna and Przemysław Borys
Department of Physical Chemistry and
Technology of Polymers, Silesian University of
Technology (SUT), Gliwice, Poland

Most of the membrane processes have both transient and stationary states. Industrial or simply practical approaches neglect, wherever possible, the transient state of the process in question. There are some good reasons for that. Namely, the transient state is the first stage of a classical (or most popular) permeation process, like gas and vapor permeation, desalination, etc., but what really matters is a well-defined stationary (steady) permeation. However, the transient state is rich in the information that may be used to characterize the process and it is worth of paying an attention to (Grzywna and Petropoulos 1983a, b; Grzywna and Frisch 1984; Grzywna and Simon 1991; Fig. 1).

Theoretically, the relation between transient and stationary fluxes reads $\lim_{t \rightarrow \infty} J^a(l, t) = J_s^a(l)$ but practically $J^a(l, t)$ reaches its steady value after the time approximately equal to $6L^a(l)$, and then it takes the form

$$J_s^a(l, t) = \overline{D} \frac{\partial c_s(x)}{\partial x} \Big|_{x=l}$$

for the downstream side of a membrane (where $c_s(x)$ is the steady state distribution of the concentration inside of the membrane – a constant

Transient Membrane Transport, Analysis of,

Transient Membrane Transport, Analysis of,
Fig. 2 Experimental configuration for the permeation experiment

gradient in case of an ideal Fickian diffusion). The experimental set-up is shown schematically in the figure below (Fig. 2).

The straight line on the mass plot also does not intersect the coordinate system at origin, but leaves a time lag equal to $L^a(l)$ which corresponds to the period where the concentration gradient builds up within the membrane (i.e., the supplied mass does not exit to the permeation side but becomes embedded into the membrane). This time lag can serve for the calculation of the diffusion coefficient (Frisch 1957; Strzelewicz and Grzywna 2008; Crank 1975; Simon and Grzywna 1993; Borys et al. 2013):

$$D = \frac{l^2}{6L^a(l)}$$

In addition, the vertical axis is cut in a position that allows to read the value of the boundary concentration c_0 (Fig. 1; Crank 1975,

Eq. 4.25 for $t \rightarrow 0$; Crank and Park 1968; Borys et al. 2013).

In a detailed analysis, except for the permeation curves on the exit side of the membrane ($J^a(l, t)$ and $Q^a(l, t)$) we can measure also the permeation on the feed side of the membrane, which results in curves of $J^a(0, t)$ and $Q^a(0, t)$. These curves also imprint the time lag, namely:

$$L^a(0) = 2L^a(l)$$

where $L^a(0)$ is the intercept of the mass permeation curve asymptotic line with the time axis (Rutherford 1997; Borys et al. 2013; Fig. 3).

Concluding, an analysis of a stationary state answers some simple but very practical questions. More refined problems need analysis of a transient state.

Except for the time lags, there is also another method for transient analysis of the diffusion process. It has been called the D₁-D₈ method for evaluation of the diffusion coefficients. It can be referred in form of a table of asymptotic formulas that can be fit to the permeation (or sorption) data. The formulas take the following forms (Grzywna and Petropoulos 1983; Rybak et al. 2009; Borys et al. 2013; Table 1):

In these formulas:

Q_t^a denotes the mass that is sorbed per unit surface in unsymmetrical sorption into the membrane after time t ,

Transient Membrane Transport, Analysis of,

Fig. 3 Transient mass flow on the feed side in the permeation experiment

Transient Membrane Transport, Analysis of, Table 1 A collection of the asymptotic formulas for the D₁-D₈ system

Analytical formula		Notes
1	$\frac{Q_t^a}{Q_\infty} = 2\sqrt{\frac{D_1}{\pi l^2}} t^{1/2}$	Unsymmetrical sorption – early time
2	$\frac{M_t^a}{M_\infty} = 4\sqrt{\frac{D_1 M_1}{\pi l^2}} t^{1/2}$	Symmetrical sorption – early time
3	$\ln\left[1 - \frac{Q_t^a}{Q_\infty}\right] = \ln\frac{8}{\pi^2} - \frac{D_2 \pi^2}{4l^2} t$	Unsymmetrical sorption – late time
4	$\ln\left[1 - \frac{M_t^a}{M_\infty}\right] = \ln\frac{8}{\pi^2} - \frac{D_2 M \pi^2}{l^2} t$	Symmetrical sorption – late time
5	$\ln[t^{1/2} J(l, t)] = \ln\left[2c_0\left(\frac{D_4}{\pi}\right)^{1/2}\right] - \frac{l^2}{4D_3 t}$	Permeation – early time
6	$\ln[Q^a(l, t) - Q_s^a(l, t)] = \ln\frac{2lc_0}{\pi^2} - \frac{D_5 \pi^2}{l^2} t$	Permeation – late time
7	$\frac{\Delta Q_t^a}{\Delta Q_\infty^a} = 4\sqrt{\frac{D_6}{\pi l^2}} t^{1/2}$	Sorption in the permeation – early time
8	$\ln[Q_s^a(0, t) - Q^a(0, t)] = \ln\frac{2lc_0}{\pi^2} - \frac{D_7 \pi^2}{l^2} t$	Permeation – late time
9	$\ln\left[1 - \frac{\Delta Q_t^a}{\Delta Q_\infty^a}\right] = \ln\frac{8}{\pi^2} - \frac{D_8 \pi^2}{l^2} t$	Sorption in the permeation – late time

$Q_\infty = c_0 l$ denotes the mass that is sorbed per unit surface in unsymmetrical sorption into the membrane after infinitely long time,

M_t^a denotes the mass that is sorbed per unit surface in symmetrical sorption into the membrane after time t ,

$M_\infty = c_0 l$ denotes the mass that is sorbed per unit surface in symmetrical sorption into the membrane after infinitely long time,

$\Delta Q_t^a = Q^a(0, t) - Q^a(l, t)$ denotes the mass that is sorbed into the membrane per unit surface after time t during permeation,

ΔQ_∞ denotes the mass that is sorbed into the membrane per unit surface during permeation after infinitely long time (in case of Fickian diffusion it is $\Delta Q_\infty = c_0 \frac{l}{2}$),

$J(l, t)$ denotes the flux on the exit side of the membrane,

$Q^a(l, t)$ denotes the mass that has permeated per unit surface to the exit side of the membrane,

$Q_s^a(l, t)$ denotes the asymptotic straight line curve of the mass per unit surface on the exit side,

$Q^a(0, t)$ denotes the mass that has permeated per unit surface to the feed side of the membrane,

$Q_s^a(0, t)$ denotes the asymptotic straight line curve of the mass per unit surface on the feed side,

c_0 is the feed concentration,

$D_1 \div D_8$ are the diffusion coefficients (equal to D in the ideal Fickian case),

t is the time.

The drawings in Fig. 4 explain the experimental set-ups and show the considered fluxes and concentration profiles within the membrane. Case (a) depicts the symmetrical sorption, case (b) depicts the unsymmetrical sorption, and case

Transient Membrane Transport, Analysis of,

Fig. 4 Experimental setups for transient membrane transport analysis and the corresponding fluxes together with concentration profiles; (a) symmetrical sorption, (b) unsymmetrical sorption, (c) permeation

(c) depicts permeation. In case of “sorption in the permeation” (based on the set-up (c)), the sorbed mass is just the integral of the concentration profile with respect to length, multiplied by the membrane surface (Fig. 4).

It is important to note the meaning of different diffusion coefficients in the above table of equations. All of these formulas are derived from the solution of a simple second Fick’s law (see the supplementary materials of Borys et al. 2013), and for simple diffusion they all have the same value, i.e., $D_1 = D_2 = \dots = D_8 = \bar{D}$. This is however no longer the case when the diffusion is non-Fickian. For example in concentration-dependent diffusion D_2 (measured mostly in the state of a terminal concentration) will provide an estimate of $D(c_{max})$ while D_1 will only provide a sort of an average of the concentration dependency. The work (Crank and Park 1968, p. 18) provides an estimate of such an average diffusion coefficient by:

$$\bar{D} = p c_0^{-p} \int (c - c_0)^{p-1} D(c) dc$$

where p should be equal to 1.67 for an increasing concentration dependency of the diffusion coefficient in sorption and 1.85 for a decreasing dependency. The raw formula, with $p = 1$ was established exactly for the stationary permeation experiment.

All of the above asymptotic formulas are presented in form of an equation $y = ax + b$,

suitable for a linear regression. For example, in the permeation experiment we can make use of equation 5 from the table and then $y = \ln[t^{1/2}J(l, t)]$, $x = \frac{1}{t}$, $a = \frac{-l^2}{4D_3}$, $b = \ln\left[2c_0\left(\frac{D_3}{\pi}\right)^{1/2}\right]$. The linear regression clearly allows to determine the constants a and b , and as a consequence the diffusion coefficients, denoted D_3 and D_4 .

Transparent Exopolymer Particle

Loreen O. Villacorte

FMC Technologies, Separation Innovation and Research Center, Arnhem, The Netherlands

Introduction

Transparent exopolymer particles (TEPs) refer to a variety of biopolymers or exopolymeric substances (EPS) in aquatic systems which can be identified by Alcian blue staining. TEPs were first described in 1993 by Alice Alldredge and coworkers (1993) shortly after discovering these materials by staining with Alcian blue dye – a cationic dye known to specifically complex with anionic groups of polysaccharides and glycoprotein (Ramus 1977). As the name suggests, TEPs are transparent organic substances seasonally abundant (e.g., algal bloom) in marine, brackish, and nonsaline surface waters (Passow 2002a; Emery et al. 1984). These substances mostly originate from exudates of phytoplankton and bacterioplankton but may also originate from macroalgae, oysters, mussels, scallops, and sea snails (Passow 2002b; McKee et al. 2005; Heinonen et al. 2007; Thornton 2004). They consist of hydrophilic, negatively charged, and mostly surface-active acidic polysaccharides containing mostly half-ester sulfate (R-OSO_3^-) and to the lesser extent carboxyl (R-COO^-) functional groups (Mopper

et al. 1995; Zhou et al. 1998). TEP has been reported to be in various forms (e.g., strings, disks, sheets, or fibers) and sizes, ranging from 3 nm in diameter up to 100 s of μm long (Berman and Holenberg 2005; Passow 2000).

For the last two decades, the presence of transparent exopolymer particles (TEPs) in seawater and freshwater and their important role in the carbon cycle in aquatic systems have been extensively studied in the field of oceanography and limnology (see review by Passow 2002a). However, their significance to membrane-based water treatment technologies has only been investigated recently. Berman and Holenberg (2005) proposed monitoring TEP in desalination plants after it was implicated as a potential cause of fouling in membrane systems. Consequently, a number of studies were conducted to investigate their presence in feedwater sources and their possible link to membrane fouling (Bar-Zeev et al. 2009; Villacorte et al. 2009a, b, 2010a, b). Moreover, the presence of TEP has also been reported in wastewater sources of membrane systems (de la Torre et al. 2008; Kennedy et al. 2009).

Identification and Measurement

Although TEP has only been known for about 20 years, the presence of transparent microscopic marine substances detectable only by staining and electron microscope had been reported way back in the 1970s (Gordon 1970; Winters et al. 1983). However, the transparent character of TEP complicated earlier studies to investigate their abundance in aquatic systems. Currently, TEP has been roughly defined as particles, recognizing that the first method used 0.4 micrometer polycarbonate membranes to extract them from the water (Alldredge et al. 1993). However, the current understanding about TEP has been changing through the years. TEPs are not real particles, as its name suggests, but rather aggregates of hydrogels which are highly deformable and can vary in size from few nanometers to hundreds of micrometers (Passow 2002a, b; Verdugo et al. 2004). Majority of these substances were formed abiotically from colloidal precursors by

spontaneous assembly of colloidal polymers in surface water (Chin et al. 1998; Passow 2000). Moreover, monitoring TEP in membrane treatment plants proved to be a challenge because MF/UF membranes can theoretically reject these materials if measured with 0.4 micrometer pore size membranes but will not totally reject their colloidal precursors which might spontaneously assemble into measurable TEP downstream. Therefore, it is increasingly important to incorporate this colloidal fraction in the TEP measurements in order to sufficiently assess the rejection by pretreatment systems. The use of liquid chromatography-organic carbon detection (LC-OCD) is a promising technique to estimate the presence of these of colloidal fraction in aquatic systems (Villacorte 2009a, b, 2010a, b; Amy et al. 2011).

Currently, there are four established methods to measure TEP. These methods either involve direct counting (Alldredge et al. 1993) or spectrophotometric measurements (Passow and Alldredge 1995; Arruda-Fatibello et al. 2004; Thornton et al. 2007), all of which involve Alcian blue staining. The spectrophotometric assay developed by Passow and Alldredge (1995) is currently the most widely used and accepted method to measure TEP. In this method, TEPs were collected through vacuum filtration on polycarbonate membrane filters (0.4 μm pore size), stained with Alcian blue, and dissolved in sulfuric acid, and then the absorbance Alcian blue bound to TEP was measured spectrophotometrically at 787 nm wavelength. Those biopolymers which passed through the filters are considered as TEP precursors or colloidal TEP ($<0.4 \mu\text{m}$; Passow 2000).

Potential Impact on Membrane Filtration and Control

TEPs comprise surface-active materials (e.g., half-ester sulfate groups) which is the main ingredient of their high stickiness (Mopper et al. 1995; Zhou et al. 1998; Dam and Drapeau 1995; Engel 2000). The relative stickiness of TEP is estimated to be between two and four orders of magnitude

higher than most other suspended particulates in surface water (Passow 2002a). TEPs may also form large gel-like materials which may function like a sponge capable of absorbing/retaining nutrients and trace elements from surface water, making them a nutritious platform and a good refuge for bacteria to grow and multiply (Alldredge et al. 1993; Berman and Holenberg 2005). Moreover, TEPs can be direct alternative carbon nutrient for bacteria as they are partially biodegradable (Passow 2002a). Based on these characteristics, Berman and company (Berman and Holenberg 2005; Berman 2010; Berman et al. 2011; Bar-Zeev et al. 2012) introduced the concept of TEP as a major initiator of biofilm development in reverse osmosis (RO) membranes. Initially, the sticky TEP material may accumulate on RO membranes (including feed spacers) and create a conditioning film conducive for bacterial attachment. Once the bacteria are attached to the film, they can effectively utilize the available dissolved nutrients (C, P, N) in the feedwater and eventually grow into large colonies. If nutrients are not limited in the system, the initial TEP layer gradually transforms into a biofilm as colonies of attached bacteria start to produce more exopolymeric substances in addition to the further accumulation of TEP from the feedwater. Current anti-biofouling strategies are usually designed to limit the influx of nutrients to the RO system by pretreatment or by applying a biocide to control bacterial population. Hence, limiting biological activity in the system may not be enough to prevent organic fouling, considering that TEP may still accumulate on the RO membrane if the pretreatment systems are not sufficiently removing them.

Although initially TEPs were only implicated as a potential problem in cross-flow NF/RO membrane systems, they are likely a major problem in dead-end membrane filtration systems (MF/UF), especially during algal blooms. With their macromolecular size (up to hundreds of micrometers), TEP can be largely (if not totally) rejected during membrane filtration. TEP may serve as a binding agent of rejected materials (e.g., particles and other organic substances) that can accumulate on membrane surfaces. Since TEPs are negatively

charged and surface-active substances, they have the high tendency to adhere to membrane surfaces than other foulants. Additionally, abundant divalent ions (e.g., Ca^{2+}) in surface water can enhance gelation of TEP by cationic bridge formation (Passow 2002). With the binding and aggregation capability of TEP, it can enhance accumulation of a cake layer on the membrane with higher hydraulic resistance and lower backwashability than other suspended materials (including algal cells). This scenario has been demonstrated in recent studies of a pilot plant treating seawater impacted by algal bloom which generated high concentrations of TEP (Schurer et al. 2012; Villacorte et al. 2010a, b). In these studies, it was also found that inline coagulation can be an effective pretreatment technique to minimize fouling of MF/UF membranes during filtration of surface of water with high concentrations of TEP.

Transport Mechanisms with Liquid Membranes

Vladimir S. Kislik
Campus Givat Ram, Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

The commonly accepted mechanism for the transport of a solute in liquid membrane (LM) is

solution-diffusion. The solute species dissolve in the liquid membrane and diffuse across the LM due to an imposed concentration gradient. Different solutes have different solubilities and diffusion coefficients in LM. According to the transport mechanisms, the LM techniques may be divided into six basic mechanisms of transport, schematically shown in Fig. 1.

In a simple transport (Fig. 1a), solute passes through due to its solubility in LM. Permeation stops when concentration equilibrium is reached. The solute does not react chemically with LM and is supposed to be in the same form in the feed (F), LM (E), and receiving, R, phases. As an example, some carboxylic and amino acids, phenol transport through xylene, decanol LM may be presented. Uphill transport and selectivity in the simple mechanism can be achieved at reaction of the solute with components of the stripping solution (see Fig. 1b). Some authors relate this technique to the facilitated transport.

The efficiency and selectivity of transport across the LM may be markedly enhanced by the presence of a mobile complexation agent (carrier) in the liquid membrane. This process is known as facilitated or carrier-mediated liquid membrane separation. The transport can be described by subsequent partitioning, complexation, and diffusion. The complex reverse reacts on the LM-receiving side interface releasing the solute which partitioning to the receiving (strip) phase (see Fig. 1c). Carriers for the selective transport of neutral molecules, anions, cations, or zwitterionic species have undergone intensive development in the last two decades.

In many cases, the facilitated transport is combined with coupling counter- or cotransport (see Fig. 1d, e) of different ions through LM. The coupling effect supplies the energy for uphill transport of the solute. Facilitated transport is markedly enhanced by the efficiency and selectivity of transport across the LM.

Active transport (see Fig. 1f) is driven by oxidation-reduction, catalytic reactions, and biochemical conversions on the membrane interfaces. As a rule, it is highly selective: no other species are transported at this type of transport. In many cases, chemical reactions in LM are

Transport Mechanisms with Liquid Membranes, Fig. 1 Schematic mechanisms of solute transport through the liquid membranes. *S* is solute to be separated, *A* are

anions cotransported, *E* is liquid membrane, *F* is feed solution, *R* is stripping solution, *red* is reduction, *ox* is oxidation

irreversible in active transport. As examples, copper transport by thioether and picrate anions by ferrocene as carriers may be presented.

The rates of chemical changes and/or rates of diffusion may control all liquid membrane transport kinetics. At least one of the chemical or diffusion steps is slow enough to control the rate of the overall transport. So, analysis of mechanisms and kinetics of the chemical and diffusion steps of the overall LM transport system is needed to find the rate-controlling ones. A universal model for all these types of transport does not exist, and the available knowledge concerning the specific interfacial processes should be taken into account in the description of real membrane process.

The basic idea of the chemical kinetics-diffusion method is that the solute presented in the different phases is considered as different chemical species obeying the laws of chemical kinetics. The general assumptions of the transport

may be formulated as: (1) Steady-state conditions of the solute transport through the phase interfaces: all fluxes are necessarily the same. (2) The overall mass-transfer rate of solute can be controlled by any of the chemical reaction-diffusion resistances in the liquid phases. (3) The overall mass-transfer resistance at steady state is the sum of individual mass-transfer resistances at diffusional regime through the boundary films and chemical reactions resistances at the phases' interface. (4) Membrane supports have uniform pore size and wetting characteristics throughout membrane. Hydrophobic membrane pore is completely wetted by organic phase; hydrophilic or ion-exchange membrane pore is completely filled with aqueous phase. (5) Thermodynamic local equilibrium at the uptake (feed-LM) and release (LM-strip) interfaces. (6) The aqueous or organic stagnant boundary films diffusion resistances may be combined with the diffusion resistances of the same liquid films (aqueous or organic) inside the

membrane pores (taking into account the membrane porosity and tortuosity) in one-dimensional series of diffusion resistances.

In all configurations (BLM, SLM, ELM) we have: (1) diffusion steps in aqueous feed and strip stagnant boundary layers, (2) diffusion of the complex solute-carrier in the LM phase and/or interdiffusion (diffusion in the filled membrane support pores), (3) partitions between aqueous feed and organic LM phases at feed-LM interface (forward extraction) and between LM and aqueous strip phases at LM-strip interface (backward extraction), and (4) kinetics of chemical interactions with formation of solute-carrier complex (complexation) and destruction of complex (decomplexation). All these steps have mathematical descriptions. (For details see BLM, SLM, and ELM entries and Kislik 2010).

Treating Pomegranate Juice, Application of Membrane Processing

Hossein Mirsaedghazi

Department of Food Technology, Abouraihan College, University of Tehran, Pakdasht, Iran

Pomegranate (*Punica granatum* L., Punicaceae) is one of the most nutritious fruits which is grown in the Middle East. Pomegranate juice in its original state has a turbid appearance which makes it difficult to preserve and undergo additional processes. Microfiltration and ultrafiltration are two pressure-driven processes which are used to clarify fruit juices.

Ultrafiltration decreases the turbidity of pomegranate juice at the same content as microfiltration

process. Other physicochemical characteristics of pomegranate juice such as acidity, total anthocyanin content, total phenolic component, antioxidant activity, and total soluble solid content similarly decrease in both ultrafiltration and microfiltration. However, microfiltration has more permeate volume than ultrafiltration which introduces it as a preferred process. On the other hand, pretreatment of pomegranate juice with microfiltration can largely increase the volume of clarified juice (Mirsaedghazi et al. 2012). Also, physicochemical characteristics of pomegranate juice are similarly changed in process using mixed cellulose ester membrane with pore sizes of 0.22 and 0.45 μm and hydrophilic polyvinylidene fluoride membrane with pore sizes of 0.22 and 0.45 μm . Evaluation of the five major anthocyanins in pomegranate juice including cyanidin 3-glucoside, cyanidin 3,5 diglucoside, delphinidin 3-glucoside, pelargonidin 3-glucoside, and pelargonidin 3,5-diglucoside and ellagic acid showed that all of them decreased after clarification with all membranes (Mirsaedghazi et al. 2010b).

Evaluation of the effect of process characteristics on permeate flux showed that the permeate flux raises with increasing membrane hydrophilic property. So, mixed cellulose ester membrane has more permeate flux than polyvinylidene fluoride one. Also, larger membrane pore size produces more clarified pomegranate juice. On the other hand, more transmembrane pressure makes more permeate flux especially in the first stages of membrane processing. However, difference between permeate flux in various transmembrane pressures is removed at the last stages of membrane processing to make a cake layer which acts as a secondary membrane. Also, rising of feed velocity increases permeate flux in all stages of clarification processing due to decrease cake layer thickness (Mirsaedghazi et al. 2010a, 2009b).

Evaluation of the fouling phenomenon in microfiltration of pomegranate juice showed that the cake formation is induced in the first stages of membrane processing and it follows by the intermediate blocking, the standard blocking, and the complete blocking, respectively. Also, cake formation was dominant mechanism of fouling in

membrane clarification of pomegranate juice (Mirsaeedghazi et al. 2009a).

Another application of membrane processing to treat pomegranate juice is concentration of juice using osmotic distillation and membrane distillation. Osmotic distillation can concentrate pomegranate juice 3.2 times. However, its antioxidant property does not change due to constant level of anthocyanins and phenol component of pomegranate juice (Cassano et al. 2011). Another research showed that osmotic distillation can increase total soluble solids of pomegranate juice from 17 to 55° Brix after about 400 min. Coupled osmotic distillation and membrane distillation can similarly concentrate pomegranate juice at 250 min. Researchers concluded that membrane processing can change parameters of pomegranate juice such as pH, total titratable acidity, color characteristics, total antioxidant activity, total phenolic content, total monomeric anthocyanins, individual phenolics, and organic acid composition. However, thermal treatment reduces such parameters in pomegranate juice (Onsekizoglu 2013).

Triptycene Polymer with Intrinsic Microporosity

Mariolino Carta
School of Chemistry, The University of
Edinburgh, Edinburgh, Scotland, UK

Triptycene and its derivatives are a class of interesting aromatic compounds with unique, concave, three-dimensional frameworks. Because of the

Triptycene Polymer with Intrinsic Microporosity, Fig. 1 Formation of the triptycene core

Triptycene Polymer with Intrinsic Microporosity, Fig. 2 Synthesis of triptycene network PIMs. R = H, Me, Et, Pr, 'Pr, Bu, 'Bu, Pent, Oct, Bz

almost perfectly trigonal shape they have been used for several different applications in the field of material chemistry. Typically the synthesis of triptycene-based compounds starts from the formation of the very reactive benzyne intermediate, for example, from the anthranilic acid, which can easily undergo Diels-Alder reaction with anthracene to form the triptycene core as shown in Fig. 1.

Probably the most important characteristic of the triptycene framework comes from the rigidity of its propeller-like structure and the guarded space between the aromatic faces which has been defined as “Internal Molecular Free Volume” (Long and Swager 2001). In fact, when functionalized triptycenes are used to form polymers, their packing in the solid state becomes very inefficient so that local cavities are created, leading to the formation of a highly microporous material. There is a great variety of examples of the use of this interesting building block for the synthesis of highly microporous materials. For instance, hexa-amino (Kohl et al. 2014) or hydroxo-based triptycenes (Taylor et al. 2014) were used to synthesize discrete molecules with

elevated microporosity. Kahveci et al. reported the use of triptycene-based molecules to make very high surface area (up to $3,800 \text{ m}^2 \text{ g}^{-1}$) covalent organic frameworks (COFs), exploiting the trigonal shape of the triptycene to form very well-defined hexagonal channels. They demonstrated the possibility of using these materials for elevated absorption of CH_4 and CO_2 at 273 K (Kahveci et al. 2013).

A series of triptycene-based network polymers of intrinsic microporosity (PIMs), reported in 2010 (Fig. 2; Ghanem et al. 2010), showed the ability of functionalized triptycenes to be used for selective gas adsorption. These networked PIMs were built from hydroxyl-substituted triptycene units with varying lengths of alkyl chains attached to the bridgehead position (R).

When polymerized with tetrafluoroterephthalonitrile via nucleophilic aromatic substitution, these monomers afforded polymers whose BET surface area varied according to the length of the alkyl chain of the bridgehead, proving the versatility of the functionalized triptycenes.

It was found that short alkyl chains (H, Me, Et, Pr) lead to highly porous materials with the

Triptycene Polymer with Intrinsic Microporosity, Fig. 3 Synthesis of 6FDI-DATRI polyimide

Triptycene Polymer with Intrinsic Microporosity, Fig. 4 Synthesis of KAUST-PI-1

highest BET surface area of $1,760 \text{ m}^2 \text{ g}^{-1}$ when $R = \text{Me}$, whereas increasing the length of the alkyl chains caused a decrease in surface area due to an elevated fraction of the generated free volume becoming occupied by the flexible side chains.

Because of the high rigidity of the bridged poly-aromatic ring, which often limits the solubility of the obtained material, there are not many examples of triptycene-based polymers that formed robust solution-processable membranes to be used for gas separation.

In the past few years, though, there have been new progresses in this field which led to the synthesis of high-performing triptycene-based materials with excellent performance for gas separation.

In 2011, Park and Cho realized a polyimide containing a diamino triptycene linked with the commercial hexafluoro dianhydride (6FDA, Fig. 3), which is one of the most used monomers for the formation of high-performance polyimides for gas separation (Cho and Park 2011). The free rotation around the imide linkage provided a low surface area (only $68 \text{ m}^2 \text{ g}^{-1}$), which limits the mass transport of the gasses into the membrane and, consequently, the permeability. Despite the low permeability, the excellent selectivities

demonstrated by this polymer allowed it to surpass the Robeson upper bound for important gas pairs such as O_2/N_2 and CO_2/CH_4 .

In order to increase the free volume, Pinnau et al. used a similar approach synthesizing an extended triptycene dianhydride with bulky isopropyl substituents on the bridgehead, polymerizing it with the commercial tetramethyl phenylenediamine. The combination of the rigidity of the bulky triptycene and the hindrance of the four methyl groups of the phenylenediamine, which restricts the rotation around the imide linkage, afforded a polyimide with very high BET surface area (KAUST-PI-1, $750 \text{ m}^2 \text{ g}^{-1}$, Fig. 4). The increase of the free volume led to high permeability which, in combination with decent selectivities, allowed them to obtain a high-performing material for gas separation (Ghanem et al. 2014).

A different method was followed by the McKeown group for the synthesis of highly porous and permeable triptycene-based polymers of intrinsic microporosity synthesized via Tröger's base polymerization (Trip-TB-PIM, Carta et al. 2014). By using a diamino triptycene and reacting it with an excess of dimethoxymethane (DMM), they obtained a polymer which combines the high rigidity of both

Triptycene Polymer with Intrinsic Microporosity, Fig. 5 Triptycene-based Trip-TB-PIM

triptycene and Tröger's base (TB) cores. The contribution of the two rigid frameworks afforded a highly microporous polymer (Trip-TB-PIM, $900 \text{ m}^2 \text{ g}^{-1}$, Fig. 5). Despite the increased stiffness of the backbone, the material resulted soluble in common solvent from which it was casted a robust self-standing thin film membrane. The combination of high surface area, which boosted the permeability, and the polarity of the TB core that enhanced the selectivities for important gas pairs allowed this triptycene-based polymer to go well beyond the Robeson upper bound for H_2/N_2 , O_2/N_2 , and CO_2/CH_4 .

Tubular Membrane

► Tubular Membrane Module

Tubular Membrane Module

Joerg Balster

Application Technology, Evonik Fibres GmbH, Schoerfling, Austria

Synonyms

[Tubular membrane](#); [Tubular module](#)

A tubular membrane module is based on tubular membranes which have the same membrane geometry as capillary membranes and hollow fiber membranes but different dimensions. Tubular membranes have an outer diameter which ranges from 5 to 25 mm (Scholz et al. 2011).

In contrast to capillaries and hollow fibers, tubular membranes are not self-supporting. Such membranes are placed inside a porous stainless steel, ceramic, or plastic tube with the diameter of the tube being, in general, more than 10 mm. The number of tubes put together in the module may

vary from 4 to 18, but is not limited to this number (Mulder 1997).

The feed solution always flows through the center of the tubes, while the permeate flows through the porous supporting tube into the module housing. Ceramic membranes are mostly assembled in such tubular module configurations. However, the packing density of the tubular module is rather low, being less than $300 \text{ m}^2/\text{m}^3$ (Mulder 1997).

Tubular modules are nowadays generally limited to ultrafiltration applications where the higher resistance against membrane fouling as an effect of the good fluid hydrodynamics outweighs the high costs (Baker 2004).

Turndown in Gas Separation

Adele Brunetti

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Turndown is the capability of the system to operate at reduced capacity (Miller and Söcker 1989). In gas separation, membrane systems are highly capable of maintaining product purity even

though the capacity is reduced down to 10 % of the initial design. This is done by either reducing feed pressure, increasing permeate pressure, or by isolating modules from the system. The first two methods can be used for short-term operation and the latter when operating at significantly reduced capacity for extended periods. No provisions are required in the design phase.

Absorption units can maintain both recovery and product purity at throughputs of ca. 30–100 % of design by adjustment of the gas streams and solvent flow rates.

Also PSA units can maintain both recovery and product purity at throughputs of ca. 30–100 % of design by adjustment of the cycle time. Between 0 % and 30 % of design product rates, purity can be maintained, but recovery is reduced unless special provisions are made in the design.

The turndown capability of cryogenic systems strongly depends on the design. Partial condensation units can maintain product purity at slightly reduced recovery at flows down to 30–50 % of design.

UF Membranes (Ultrafiltration Membranes)

Herb Lutz
EMD Millipore Corporation, Playa del Rey,
CA, USA

UF membranes are thin porous solids that perform separations by retaining and passing solutes primarily based on their size. Key membrane properties include retention capability, solvent permeability, chemical compatibility, mechanical strength for module fabrication and repeated use, consistency, and cost. They have nominal molecular weight limit (NMWL) ratings of 1–5,000 kDa to retain solutes such as macromolecules, nanoparticles, and colloids while passing smaller solutes and solvents. UF membranes retain smaller solutes than microfiltration membranes and larger solutes than reverse osmosis membranes. Food and medical applications require extractable testing, adsorption, shedding, and United States Pharmacopeia (USP) class VI toxicity testing. In addition, these applications require high consistency membranes with vendor quality programs (e.g., International Organization for Standardization (ISO), current good manufacturing practices (cGMP)). With reuse, membrane cost is significantly reduced.

UF membranes primarily consist of polymers (polyethersulfone, regenerated cellulose, polysulfone, polyamide, polyacrylonitrile, or various

fluoropolymers) formed by immersion casting on a web or as a composite cast on an MF membrane. A multicomponent, high polymer concentration (5–25 %) viscous solution (lacquer) is well mixed, degassed, and filtered to remove particles or trap air. The lacquer contains a nonsolvent which separates into droplets and becomes the pores of the UF membrane. Hollow fibers are formed by metering the lacquer through a die into an immersion bath. Flat sheet membrane is formed by metering the lacquer through a precisely controlled slot to coat a support web lying on a casting drum. Early UF immersion cast membranes cast on a solid web had thin surface retentive layers with an open structure underneath. These membranes were prone to defects and showed poor retention and consistency. Newer composite membranes use a MF membrane as the support web with the UF layer cast on top. These composites demonstrate consistently high retention and can be integrity tested using air diffusion in water.

The web coat or extruded fiber is fed into an immersion liquid bath that causes the lacquer solvent to diffuse out of the lacquer coat (desolvation). Then solubility limits are reached (demixing) where the nonsolvent phase nucleates and grows (spinodal decomposition) and the solid polymer phase nucleates and grows (gelation). The polymer structure then coalesces into its final structure (phase transformation). The membrane structure is formed rapidly at nonequilibrium conditions, but the trajectory is

UF Membranes (Ultrafiltration Membranes), Table 1 UF membranes

Material	Advantages	Disadvantages
Polyethersulfone (PES)	Resistance to temperature, Cl ₂ , pH, easy fabrication	Hydrophobic
Regenerated cellulose	Hydrophilic, low fouling	Sensitive to temperature, pH, Cl ₂ , microbial attack, mechanical creep
Polyamide		Sensitive to Cl ₂ , microbial attack
Polyvinylidene fluoride (PVDF)	Resistance to temperature, Cl ₂ , easy fabrication	Hydrophobic, coating sensitive to high pH
Inorganic	Resistance to temperature, Cl ₂ , pH, high pressure, solvents, long life	Cost, brittleness, high cross-flow rates

commonly plotted on a ternary phase diagram. Foam or nodular structures form depending on the formation path. Asymmetry or skin structures can form depending on the kinetics of diffusive transport and nucleation. The key control parameters are the composition of the lacquer, composition of the immersion bath, coating or extrusion thickness, casting speed, bath temperature, and bath flow velocity.

Residual solvent and anti-solvent are washed out of the polymeric membrane structure in separate extraction baths. Hydrophobic polymers are surface modified to render them hydrophilic and thereby reduce fouling, reduce product losses, and increase flux.

Inorganic UF membranes (alumina, glass, and zirconia) are formed by sintering. Layers of spherical particles are deposited on a substrate and heated to fuse them together. Pores are formed in the gaps between the spherical particles. Successive layers of smaller and smaller particles can be deposited to make tighter membranes. These membranes find use in corrosive applications where their high cost can be justified (Table 1, Fig. 1).

UF Modeling (Ultrafiltration Modeling)

Herb Lutz

EMD Millipore Corporation, Playa del Rey, CA, USA

Basic membrane process configurations include single-pass, batch, fed-batch, and continuous operation (Fig. 1). Single-pass operation involves a single pass of feed through the module feed channel where it exists as sufficiently concentrated retentate. This requires a long residence time in the modules using long feed channels and/or low feed flow rates. Component concentrations change along the length of the retentate channel. Analysis starts with the steady-state component and solvent mass balances as shown in the Table 1. These consider an incremental area

element, dA , in the axial or flow direction for a feed channel, module, or membrane assembly of constant width. Constant density is also assumed. Combining the balance equations and integrating yields a relation between concentrations, volume reduction, and solute passage. The area required for processing is obtained by integrating the solvent balance. The Cheryan flux approximation $\bar{J} = 0.33J_{\text{initial}} + 0.67J_{\text{final}}$ is useful. Flux decreases along the feed channel due to a reduction in pressure by friction, a reduction in crossflow due to permeate losses, and an increase in osmotic pressure due to concentration increases in the retained solute. Eventually, conditions in the feed channel reach an osmotic pinch point where there is no net driving force for the flow. Beyond this point, the flow may run in a reverse direction. To solve for details of the flow, one needs an appropriate flux model relating flux to cross flow, concentration, and pressure and a hydraulic model showing how retentate pressure profiles vary with flow for feed spacer-filled channels. One can use simplified linear or gel flux models as an approximation.

Continuous operation (also called feed and bleed) is similar to single-pass operation but

involves partial recycle of the retentate. This configuration allows a higher crossflow and higher membrane fluxes compared to single pass for concentrated systems running in the polarized region of the flux curve. Compared to batch operation, setup and cleaning times between batches are significantly reduced so there is higher productivity on invested capital. As a result, continuous systems are common for large-scale processing. Continuous operation is frequently performed as a multistage operation where the retentate from one system becomes the feed for the next system. Each stage runs at a different concentration and the total area requirements are less than for a single stage. After about four stages, the system approaches batch operation as a minimum area. The residence time and number of pump passes is in-between single-pass and batch operation, depending on the fraction of retentate recycled.

Batch operation involves recycling the retentate to the feed tank to create a multipass flow of the feed through the module. The compositions in batch systems change over time. High flow rates generate better fluxes but recycling is necessary to generate either the desired permeate flow or a concentrated retentate. Multipass operation increases residence times and pump passes that may degrade retentate components. For systems requiring high pressures to generate permeate flow, it is useful to run the entire system at high pressure to save energy. As before, unsteady-state solvent and component mass balances can be written for batch operation and combined and integrated to yield concentration behavior. TFF systems have a maximum volume reduction capability, typically about 40x. This arises because tanks must be large enough to hold the batch volume while allowing operation at a minimum working volume. The minimum working volume may be limited by air entrainment into the feed pump, mixing in the feed tank, or level measurement capabilities.

Fed-batch operation extends the volume reduction capability to 100x and provides some flexibility in processing a variety of batch volumes in a single skid. For a fed-batch operation, the retentate is returned to a smaller recycle tank, not

the large feed tank. Feed is added to the recycle tank as permeate is withdrawn to maintain a constant recycle tank volume. The recycle tank can allow a smaller working volume without entrainment. Reducing the size of the recycle tank results in just a section of the pipe or bypass line that returns the retentate directly into the pump feed. Fluid from the feed tank is added slowly into this recirculation loop. This allows a holdup volume consisting of just the recirculation loop. This configuration can be problematic to flush, vent, and drain leading to cleaning and product recovery issues. Fed-batch retentate concentrations exceed the batch concentrations until the curves intersect and any further concentration would proceed in batch mode. The benefits sought from higher concentrations can lead to other problems such as reduced fluxes, larger area and pumps, possible denaturation, and extra lines that may have issues with cleaning and product recovery. This has not only caused significant commissioning and validation delays but also led to the scrapping of a process skid as unworkable. The number of pump passes will also be higher, leading to more potential solute degradation. Fed batch and bypass should be used only when necessary.

Diafiltration mode involves adding a new buffer to the system while withdrawing permeate at the same rate so the tank level remains constant. Over time, the retained solute sees a buffer change. This is characterized by the diavolumes N , the ratio of buffer volume added to tank volume for batch systems, and the ratio of buffer flow to feed flow for continuous systems. Table 1 shows how solute concentrations change with N . A fully retained solute ($S_i = 0$) maintains its retentate concentration constant at the initial value. For fully passing solutes, >4.5 diavolumes are needed to achieve a specification of $<1\%$ of the original buffer components. Incomplete mixing (due to dead legs and liquid droplets on tank walls) becomes significant at high diavolumes. It is common to add an extra 1–2 diavolumes as a safety factor to ensure complete buffer exchange. For final formulation pharmaceutical applications, 8–10 diavolumes are standard.

Diafiltration usually takes much more time than concentration. When a fully retained solute controls the flux by the gel model, the batch diafiltration time is given by

$$t = \left(\frac{V_a}{A}\right) \left(\frac{N/X}{k \ln \left(\frac{C_g}{C} \right)} \right), \text{ where } C \text{ and } X \text{ are related}$$

as in Table 1. This equation shows that more initial volume reduction and higher concentration lead to reduced batch volume and lower diafiltration fluxes. A minimum time solution exists when $C = C_g/e$.

UF Transport (Ultrafiltration Transport)

Herb Lutz

EMD Millipore Corporation, Playa del Rey,
CA, USA

UF membranes are porous solids that selectively retain large solutes and pass liquid solvent and small solutes. The interconnected porous network is sometimes described as a percolating foam structure. It is commonly described by a lognormal distribution of parallel cylindrical pores. Laminar flow of pure solvent through an incompressible membrane follows Darcy's law $J = L_m \cdot TMP$ where J is the flux or volumetric flow per unit membrane area, TMP is the transmembrane pressure difference across the membrane, and L_m is the constant membrane permeability. For parallel cylindrical pores of the same radius r , the permeability is $L_m = \frac{er^2}{8\mu l}$ where ε is the membrane porosity, μ is the fluid viscosity, and l is the membrane thickness. Any retained solute will accumulate on the upstream membrane surface causing an osmotic pressure Π . Membrane fouling reduces the membrane permeability to L_f . Process flow is described by the osmotic model $J = L_f(TMP - \sigma_0 \Delta \Pi)$ where σ_0 is the osmotic or Staverman reflection coefficient. For a totally retained solute, $\sigma_0 = 1$, and for a totally passing solute, $\sigma_0 = 0$. When $TMP < \Delta \Pi$, reverse flow is observed.

Retained solute will continue to accumulate for flow normal to the membrane surface J (normal flow filtration or NFF) but will reach a steady state when flow tangential to the surface v is added (tangential flow filtration or TFF). Most UF is run in TFF mode to maintain high fluxes for economical operation. For steady state where back diffusion balances entrained solute convected to the surface, the wall concentration $C_w = C_b \exp(J/k)$ for bulk concentration C_b , flux J , and mass transfer coefficient k . Retained solutes are reversibly held in a polarization or "gel" layer at the membrane surface at $\sim 1 \text{ g/m}^2$. The solute concentration at the membrane surface or "wall" operation at low concentrations (linear region) follows Darcy's law, but operation at high concentrations (polarized region) results in a flux that is independent of TMP but dependent on tangential flow v and solute bulk concentration C . This is empirically described by the gel flux model $J = kv^n \cdot \ln(C_g/C)$ where kv^n is the mass transfer coefficient and C_g is a constant "gel point" wall concentration. An actual gel is not formed. The osmotic model describes the flux across the linear and polarized regions. These models strictly apply to a uniform upstream, while in membrane modules, properties change along the upstream channel. The models can be integrated along the feed channel but are commonly used with an average TMP across the feed channel and feed velocities and concentrations.

A hydrodynamic analysis of steady-state solute flux by diffusion and convection along a pore yields a net solute flux of $N = [\phi K_c J / \varepsilon] [C_{wall} \exp(Pe_m) - C_{permeate}] / [\exp(Pe_m) - 1]$. The membrane Peclet number is $Pe_m = [Jl/D_\infty] [\phi K_c / \varepsilon \phi K_d]$ for solute-free solution binary diffusivity D_∞ , partitioning coefficient ϕ , convective hindrance coefficient K_c , and diffusive hindrance coefficient K_d . Pore shapes fall in-between cylindrical and slit geometries in terms of solute and pore wall interactions. For a spherical solute in a cylindrical pore, $C_{pore}/C_{wall} = \phi = (1 - \lambda)^2$ where $\lambda = r_{solute}/r_{pore}$, while asymptotic analysis yields $K_c \approx [2 - (1 - \lambda)^2] \exp(-0.7146\lambda^2)$ and $K_d \approx (1 - \lambda)^{-13/2}$. For a

spherical solute in a slit pore, steric considerations imply an equilibrium partitioning $C_{\text{pore}}/C_{\text{wall}} = \phi = (1 - \lambda)$ where $\lambda = r_{\text{solute}}/r_{\text{pore}}$, while asymptotic analysis yields $K_c \approx (3 - \phi)^2 [1/2 - \lambda^2/6]$ and $K_d \approx (1 - 1.004\lambda + 0.418\lambda^3 + 0.21\lambda^4 - 0.619\lambda^5)$. The “actual” solute sieving coefficient becomes $S_a = C_{\text{permeate}}/C_{\text{wall}} = S_\infty \exp(\text{Pe}_m) / [S_\infty + \exp(\text{Pe}_m) - 1]$ where $S_\infty = \phi K_c = 1 - \sigma_0$ is the asymptotic sieving coefficient for large Pe_m where convection dominates. The presence of surface charges reduces both membrane permeability and solute sieving coefficients. Average sieving across a membrane thickness from the wall to the permeate requires integration across the pore size distribution. Measured sieving coefficients from the bulk feed to the permeate requires accounting for polarization. Solutes are diluted within pores, but multicomponent interaction is required within the polarization layer where large solute polarization reduces the sieving of smaller solutes. Sieving along devices requires integration along the feed channel.

Ultrafiltration (UF)

Herb Lutz

EMD Millipore Corporation, Playa del Rey, CA, USA

Ultrafiltration (UF or UF/DF) is a unit operation that separates large solutes from small solutes and solvents. Larger pore membranes are referred to as microfiltration (MF), while smaller pore filters are referred to as reverse osmosis (RO). There is some nomenclature confusion as membrane scientists refer to a loose RO charged membrane as a nanofilter, while bioprocessors refer to a loose UF membrane as a nanofilter that removes nanometer-sized viruses.

UF employs thin porous solid UF membranes as either flat sheets or tubes (see chapter “► [UF Membranes \(Ultrafiltration Membranes\)](#)”). These perform separations by retaining and passing solutes primarily based on their size and secondarily based on solute-surface interaction by charge or

other fields (see chapter “► [UF Transport \(Ultrafiltration Transport\)](#)”). Pressures of 0.2–1.0 MPa drive liquid solvents (primarily water) through the membrane. Since retained solid buildup can cause the solute flow to rapidly decline, most UF systems are run in tangential flow filtration (TFF) mode with a significant velocity tangent to the membrane surface. This enhances back transport away from the surface and leads to steady-state operation at reasonably economical solvent fluxes (volumetric flow per unit area).

UF membranes are fabricated into modules that allow for convenient assembly and operation in modular systems. Commercial module formats include hollow fiber bundles, tubular assemblies, spiral wound assemblies, and cassettes. Stirred cell devices are commonly used for research since they require little volume, operate at uniform conditions across their surface, and are well characterized.

Typical UF process operating steps include: assembly, water flush, integrity testing, buffer flush, processing, recovery flush, cleaning, sanitization, disassembly, and storage. Assembly of modules into a holder is required for a new operation or when the filters have reached expiration and need to be replaced. Water flushing thoroughly wets the membrane and removes extractables and antimicrobial or humectant storage agents. Integrity testing involves measuring downstream airflow with pressurized air upstream. Defects or installation leaks will show up as high air flows. Buffer flush conditions the membrane to limit product denaturation and membrane fouling. Processing may follow concentration or diafiltration in continuous or batch operating modes (see chapter “► [UF Membranes \(Ultrafiltration Membranes\)](#)”). Diafiltration involves adding a new buffer that displaces the old buffer leaving in the permeate while retaining the desired solute. Recovering high value product from batch systems involves a low pressure air blowdown or reverse buffer flush through the modules. System cleaning involves thoroughly flushing out remaining product and recirculating a cleaning solution at the desired time, temperature, and concentration. Multiple fouling agents

may require cleaning steps with multiple cleaning agents (e.g., NaOH for proteins, acid for precipitated salts). Cleaning effectiveness is measured by the restoration of water permeability. Sanitization involves recirculating a sanitizing solution at the desired time, temperature, and concentration. This is frequently done as a separate additional step even if the chemical is the same as for cleaning. The rationale is to ensure that no protective biofilm is present that would prevent sanitization from being effective. At the end of a production campaign, modules can be stored in a liquid storage solution. Modules at the end of their life are discarded. Lifetimes can be set by number of uses, age, or process performance such as permeability, retention, integrity, and feed channel pressure drop.

Key UF membrane properties include retention capability, solvent permeability, chemical compatibility, mechanical strength for module fabrication and repeated use, consistency, and cost. UF membranes come with a nominal molecular weight limit (NMWL) rating of 1.0–5,000.0 KDa. The smaller rating means a tighter filter able to retain a smaller solute with a lower molecular weight. While these ratings are convenient for testing and rough selection, solute retention is based on effective solute dimensions and not on molecular weight. Nonspherical solutes will orient themselves under shear so that their major axis is parallel to the pores. Linear chain dextrans and DNA show a higher passage than globular proteins of the same molecular weight. The effective solute radius can increase more than four times as a result of surface charge. Ratings are not standardized among vendors and depend on the marker solute selected (e.g., protein, dextran in a particular buffer) and the level of retention selected for the marker solute (e.g., 90 %). Retention is also affected by fouling due to adsorbed components and polarized solutes on the membrane surface. A rule of thumb for selecting membrane NMWL is to take 0.2–0.3 of the MW of the solute that is to be retained by the membrane. This should be taken as a rough guide to select membranes for testing.

Selected membrane module manufacturers in 2012 include: EMD Millipore (Billerica, MA, USA), Pall (Port Washington, NY, USA),

Sartorius (Germany), Asahi Kasei (Japan), GE Energy (Raytown, MO, USA), Siemens (Warrendale, PA, USA), TriSep (Goleta, CA, USA), Aquatech (Canonsburg, PA, USA), Degremont Technologies (Richmond, VA, USA), Spintek (Los Alamitos, CA, USA), Koch Membrane Systems (Wilmington, MA, USA), Berghof (Mühlhausen, Germany), Daicel (Tokyo, Japan), DSS (Silkeborg, Denmark), Matrix (Oceanside, CA, USA), and Nitto Denko Hydranautics (Oceanside, CA, USA).

Ultrafiltration Applications

Herb Lutz

EMD Millipore Corporation, Playa del Rey, CA, USA

UF membranes perform separations based on solute size. They have retention ratings of 1–5,000 K for roughly spherical solutes and can retain solutes of 10–1,000 Å or larger in diameter (roughly 300–1,000 KDa) such as colloids, large molecules, and nanoparticles. Smaller solutes and solvents pass through the ultrafilter. UF membranes retain smaller solutes than microfiltration membranes and larger solutes than reverse osmosis membranes.

Most commercial operations are run as tangential flow filtration (TFF), but dilute solutions such as water treatment or small-scale sample preparation are run as normal flow filtration (NFF). Virus-retaining filters, sometimes referred to as nanofilters, are on the most open end of UF and

Ultrafiltration Applications, Table 1 Ultrafiltration applications

Module	Fibers	Spirals	Cassette	Fibers	Tubes
System	Continuous	Continuous	Batch, NFF	Continuous	Batch
Performance drivers	Cost, plugging	Cost	Recovery	Cost	Plugging, cost

can be run as NFF or TFF. The first large commercial application of UF was paint recycling, followed by dairy whey recovery in the mid-1970s. Applications can be described as clarification of a permeate product (e.g., water purification), concentration of a retentate product (e.g., paint, dairy, and pharmaceuticals), or solute purification (e.g., virus/protein separation and buffer exchange). UF applications are enabled by low temperature and low-cost operation, particularly with membrane reuse. UF processes can vary significantly between applications due to differing requirements and relative costs.

Automobiles used to rust due to paint nonuniformity. Electrodeposition of cationic paint resin on automobiles (connected to the cathode) was developed to provide a uniform, defect-free coating with high corrosion resistance. This process deposits about 50 % excess paint on the surface that must be washed off. UF is used to retain and recover the washed paint to maintain a high paint concentration in the paint bath. The paint-free permeate is used for washing. Paint recovery to reduce losses and lower system costs makes the process economical.

During cheese making, the coagulated milk or curd is used to make cheese, while the supernatant whey is a waste product rich in salts, proteins, and lactose. UF retains whey proteins while passing water, sugars, and salts. The retentate proteins are used as soft cheese products and animal feed supplements. The MMV process concentrates the milk by UF after centrifugation removes the cream and before coagulation to improve yields and reduce disposal costs.

UF is used in biopharmaceutical purification to retain proteins, viruses, bacterial vaccines, and nucleic acids. Water and buffers pass through the membrane. Initial UF concentration of clarified

fluids or lysates reduces process volumes to decrease subsequent column sizes and increase binding. Diafiltration UF changes buffer conditions (for loading on to columns) and to concentrate and change buffers (for final formulation into a storage buffer). For drug products with potential viral contaminants (sourced from mammalian cells or human and animal blood plasma), virus removal filters employed in either a TFF or NFF mode retain the viruses, while the drug product is recovered in the permeate. UF has displaced size exclusion chromatography (SEC) for buffer exchange due to its lower cost and ability to run higher protein concentrations. These applications require high yields, maintaining high purity, consistent operation, and scale-up of the valuable product.

UF is used to clarify various fruit juices (apple, grape, pear, pineapple, cranberry, orange, and lemon) which are recovered as the permeate. UF has also been used to remove pigments and reduce browning in wine production. Low-cost operation is required.

Wastewater treatment and water purification applications employ UF in a TFF or NFF mode to produce permeate product with reduced colloids, pyrogens, and viruses. Oil droplets in wastewater are retained by UF for recycle or disposal at significantly reduced volumes (Table 1).

Ultrafiltration Membrane Bioreactor

Zhiwei Wang

Department of Environmental Engineering,
College of Environmental Science and
Engineering, Tongji University, Shanghai, China

Synonyms

Membrane bioreactor using ultrafiltration membranes

Introduction

Membrane bioreactor (MBR) is the combination of a membrane process with an activated sludge bioreactor and is now widely used for municipal/domestic and industrial wastewater treatment. Pressure-driven membrane separation is usually applied in MBR processes even though other novel membrane separation systems (e.g., forward osmosis membrane) have been developed. Typical pressure-driven filtration types that could be used in MBRs include dynamic membrane filtration, microfiltration (MF), ultrafiltration (UF), and nanofiltration (NF) (Wang et al. 2008; Meng et al. 2009), while MF and UF membranes are commonly used (Wang et al. 2008). MBRs using UF membrane can be termed as ultrafiltration MBRs.

In UF processes, suspended solids and solutes of large molecular weight present in feed solutions (e.g., water and wastewater) are retained while water and low molecular weight solutes pass through the membrane and flow into the permeate. The membrane pore size of UF is generally in the range of $0.002 \sim 0.1 \mu\text{m}$, and the corresponding molecular weight cut-off (MWCO) roughly ranges from 1 to 500 kDa. The transmembrane pressure (TMP) of UF is about $0.1 \sim 0.7 \text{ MPa}$. Commercial UF membranes are usually asymmetric with a thin skin layer ($0.1 \sim 1.0 \mu\text{m}$ thick) and a highly porous layer ($50 \sim 250 \mu\text{m}$ thick) (Xiarchos et al. 2003), although some symmetric membranes are also available. The porous skin

layer of UF membranes is usually exposed to the feed solutions. Typical UF membrane materials include polyvinylidene fluoride, polyether-sulphone, polyacrylonitrile, polyimide, polytetrafluoroethylene, polypropylene, polysulfone, cellulose acetate, aliphatic polyamides, and ceramics (e.g., zirconium and aluminum oxides) (Xiarchos et al. 2003; Wang et al. 2008). Due to the introduction of membrane separation, MBRs have several prominent advantages including improved effluent quality, higher volumetric organic load, reduced footprint, and less sludge production compared to conventional activated sludge (CAS) processes, and thus have attracted much attention in the past two decades.

In UF MBR processes, MBR systems are generally comprised of two configurations: submerged (immersed or integrated) MBRs and side-stream (recirculated or external) MBRs (see Fig. 1) based on whether the membrane modules are immersed in the main reactor or not. In general, submerged MBRs consume much less energy than side-stream MBRs due to the absence of a high-flow recirculation pump. Compared with side-stream MBR, submerged MBR is more popular in water and wastewater treatment because of its lower operational cost (Wang et al. 2008). Side-stream MBRs are widely used for industrial wastewater treatment.

Membrane fouling is inevitable for MBRs, resulting from the interactions between the membrane material and the components of activated sludge (biomass). The potential foulants include suspended solids, colloids, biopolymers (e.g., soluble microbial products and extracellular polymeric substances), and so on, while biopolymers are currently regarded as major contributors to membrane fouling (Meng et al. 2009; Wang et al. 2013). Membrane filtration performance can be enhanced through modifying membrane materials, optimizing operating conditions, and bettering sludge characteristics. Membrane cleaning is periodically performed for maintaining the sustainable operation of MBRs during long-term operation. The well-designed cleaning protocols are comprised of backwashing, chemically enhanced backwashing, maintenance cleaning, and recovery cleaning. The prevalent

Ultrafiltration Membrane Bioreactor, Fig. 1 MBR configuration: (a) side-stream membrane bioreactor; (b) submerged membrane bioreactor

cleaning agents include NaOCl (sodium hypochlorite) and citric acid targeting organic fouling and inorganic fouling, respectively. In general, cleaning-in-place is preferred while offline cleaning is needed in MBRs if the filtration performance cannot be sustained by using online cleaning.

Ultrafine Nanofibers

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu
Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Ultrafine nanofibers are nanofibers with typical fiber diameters ranging from 1 to about 10 nm. They can be fabricated by using a variety of techniques, such as self-assembly, electrospinning, or chemical catalysis. A novel technology has been developed to fabricate ultrafine polysaccharide nanofibers (e.g., ultrafine cellulose nanofibers) by using a combination of chemical and mechanical treatments on natural resources, such as wood, cotton, and crab/shrimp shell (chitin) (Ma et al. 2011). The fiber diameter of the achieved ultrafine nanofibers was 5–15 nm with various fiber lengths of a few hundred nanometers to a few microns. The chemical treatment, typically, is a selective oxidation of C6-hydroxyl groups in cellulose with the TEMPO/NaBr/NaClO aqueous system. After oxidation, a mechanical treatment, such as grind, sonication, or/and homogenization, is applied to defibrillate the fiber bundles. Therefore, ultrafine cellulose nanofibers with nominal fiber diameters of 5–15 nm in aqueous suspension can readily be obtained.

Ultrafine Nanofibers, Fig. 1 Ultrafine nanofibers from different natural polysaccharide sources (Ma et al. 2012b)

The fabricated ultrafine cellulose nanofibers offer many unique advantages, including (1) high surface-to-volume ratio ($\sim 600 \text{ m}^2/\text{g}$); (2) high chemical resistance and strong mechanical properties; (3) super-hydrophilic surface property; (4) surface functionalized with carboxylate groups, hydroxyl groups, and/or aldehyde groups; (5) water dispersible and stable suspensions; (6) and benign environmental properties. Based on these advantages, one of the novel applications of ultrafine cellulose nanofibers is that cross-linked ultrafine fibers can be used as a barrier layer in a highly permeable nanocomposite membrane for water purification. The super-hydrophilic surface of the ultrafine cellulose

nanofibers is also of benefit to the antifouling property of the membrane. Most importantly, directed water channels can be formed between the surface of ultrafine (cellulose) nanofibers and the surface of the barrier polymer matrix, thereby significantly increasing the permeability of the membrane without losing the rejection ratio (Ma et al. 2012a, b) (Fig. 1).

Ultrahigh Molecular Weight Polyethylene

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

Ultrahigh molecular weight polyethylene (UHMWPE), also known as high-modulus polyethylene (HMPE), is a subset of the thermoplastic polyethylene. Polyethylene is a polymer formed from ethylene (C_2H_4), which is a gas having a molecular weight of 28 g/mol. The generic chemical formula for polyethylene is $-(C_2H_4)_n-$, where n is the degree of polymerization. A schematic of the chemical structures for ethylene and polyethylene is shown in Fig. 1.

There are several kinds of polyethylene (LDPE, LLDPE, HDPE, UHMWPE), depending upon the degree of polymerization or molecular weights and chain architectures. LDPE and LLDPE refer to low-density polyethylene and linear low-density polyethylene, respectively. These polyethylenes generally have branched and linear chain architectures, respectively, each with a molecular weight of typically less than 50,000 g/mol. High-density polyethylene

(HDPE) is a linear polymer with a molecular weight of up to 200,000 g/mol (Steven 2009).

For an ultrahigh molecular weight polyethylene, the molecular chain can consist of as many as 200,000 ethylene repeat units. Thus, molecular weight ranges in the millions, usually between two and six million. The longer chain serves to transfer load more effectively to the polymer backbone by strengthening intermolecular interactions. This results in a very tough material, with the highest impact strength of any thermoplastic presently made (Stein 1999). UHMWPE is a unique polymer with outstanding physical, chemical, and mechanical properties. Most notable are its chemical inertness, lubricity, impact resistance, and abrasion resistance. Table 1 summarizes the physical and mechanical properties of UHMWPE.

Owing to its excellent properties, UHMWPE is widely used as a biomaterial such as in orthopedics as a bearing material in artificial joints. One of the major limiting factors of UHMWPE implant is its wear and damage with time, thus having only a finite lifetime. Cross-linking of the UHMWPE chains is found to be the promising method to dramatic reductions in wear, improving the performance in biomedical applications (Steven 2004).

Recently, research has been conducted for the modification of the UHMWPE surface by grafting with different techniques such as radiation, chemical, and plasma grafting. Since UHMWPE

Urease Immobilization on Membranes

Sacide Alsoy Altinkaya
Department of Chemical Engineering, Izmir
Institute of Technology, Urla, Izmir, Turkey

Enzyme immobilization within membrane pores or onto membrane surface has gained growing interest due to controllable transport of reaction substrates and products through the membrane. This is particularly important when the product acts as an inhibitor. Also, high surface area of the membranes offers a potentially higher enzyme loading. Urease is an enzyme most extensively studied for immobilization and catalyzes the

hydrolysis of urea to ammonium and carbon dioxide. Nonenzymatic urea hydrolysis requires high temperatures and pressures and biological conversion of urea nitrogen to dinitrogen suffers from instabilities of microbial bed. The method based on the hydrolysis of urea by urease immobilized on a suitable support material is an attractive and an alternative removal method.

The choice of a support material for enzyme immobilization is important to minimize the loss of enzyme activity. The membrane material should have high affinity to proteins, available reactive functional groups for direct enzyme attachment or for chemical modification, mechanical stability, and regenerability. The membranes from natural polymers may have restricted applications since the abundance in hydrogen bonding among the polymer chains may result in a decrease in flexibility, the excellent affinity to proteins may make them easily eroded by bacteria, and high hydrophilicity may cause the membranes to swell in a wet atmosphere. Due to these drawbacks, synthetic membranes were preferred as enzyme carriers because of their low cost, easy surface modification, resistance to biodegradation, and thermal and chemical stabilities.

Urease was immobilized onto various supports and a detailed review of these studies has been published by Krajewska (2009). The membranes used as a support material were made from nylon, silk cloth, polypropylene fabric, poly(hydroxyethyl methacrylate-*co*-glycidyl methacrylate), polyacrylonitrile, methoxypolyethylene glycol 5000, poly(*N*-isopropylacrylamide-*co*-*N*-acrylosuccinimide-*co*-2-hydroxyethyl methacrylate), poly(2-hydroxyethylmethacrylate), chitosan-poly(glycidylmethacrylate) copolymer, ethylene-vinyl alcohol, nylon 6/6, acrylamide-grafted poly(ethylene terephthalate) fibers, tris(hydroxymethyl)phosphine polyetheramine copolymer, chitosan, collagen-glycidyl methacrylate graft polymer, cyanuric chloride DEAE-cellulose ether, poly(acrylonitrile)-chitosan composite, expanded PTFE, polyethylene, polyamide, polyaniline, poly(ethylene terephthalate) fibers, and aminated polysulfone. In these studies, urease was immobilized by covalent attachment where reactive functional groups on the surface of the

membrane were generated by different surface modification techniques and by cross-linking with multifunctional, low molecular reagents. In recent years, the layer-by-layer assembly technique was shown to be an efficient method for enzyme immobilization (Smuleac et al. 2006). The method involves layer-by-layer deposition of oppositely charged polyelectrolytes by consecutive, alternating immersion of a charged substrate into aqueous solutions of an anionic and a cationic polyelectrolyte. Since enzymes are multiply charged molecules, the layer-by-layer (LBL) assembly offers a simple method to perform the immobilization. In some cases, electrostatic interactions in the assembly help stabilize the enzymes to maintain their activity. The LBL method was used to immobilize urease on polystyrene particles, silicon microchannels, or NH_3 electrode (Krajewska 2009). Guedidi et al. (2010) immobilized urease on polyacrylonitrile-based membranes using LBL assembly. The optimum pH for both native and immobilized urease was found to be at about seven. Immobilized form of urease retained higher activity at lower pH than the soluble counterpart. Immobilization onto a polyelectrolyte layer (urease forms the last layer of the assembly) resulted in a higher catalytic activity than that of enzyme directly immobilized on the membrane which clearly indicates the beneficial effect of a polyelectrolyte environment. Immobilization of urease in between two polyelectrolyte layers decreased the activity compared to the previous case most probable due to the diffusion-limited accessibility of the catalytic site. Adsorption of negatively charged urease directly onto negatively charged support resulted in a loss of enzyme activity in a short period of time. On the other hand, immobilization of urease between two polyelectrolyte layers appeared to bring better environment to ensure long-term enzyme stability.

Use of Microalgae in MBR

Baoqiang Liao

Department of Chemical Engineering, Lakehead University, Thunder Bay, ON, Canada

Membrane photobioreactor is a system that integrates microalga growth with membrane separations for nutrient (N and P) removal from wastewater and algal biomass production for biofuels, as shown in Fig. 1.

Commercial use of algal cultures for wastewater treatment and mass production of algal biomass has a history over one century. Biological wastewater treatment with microalgae is particularly attractive due to their photosynthetic capabilities in converting solar energy and CO_2 into useful biomass and uptaking nutrients (nitrogen and phosphorus) into microalgae biomass (Rawat et al. 2011). The use of membrane bioreactors for microalgae wastewater treatment simplifies the operation of microalgae harvesting and produces effluent with superior quality. Membrane bioreactor (MBR) has been widely used for municipal and industrial wastewater treatment, due to the advantages of small footprint, high productivity, and superior quality of effluent for water reuse and system closure. However, nutrient (N and P) removal has been a challenge for both aerobic MBR and anaerobic MBR. The capability of microalgae for nutrient uptake and CO_2 as carbon source for growth makes it an ideal candidate for sustainable wastewater treatment. The integrated MBR-microalgae processes have received much attention in recent years as a next-generation

Use of Microalgae in MBR, Fig. 1 Schematic diagram of a membrane photobioreactor (Adapted from Xu et al. (2014))

technology for sustainable wastewater treatment. There are three types of microalgae membrane bioreactor processes: (1) an integration of conventional activated sludge process with membrane photobioreactor, (2) an integration of MBRs (aerobic MBR or anaerobic MBR) with conventional microalgae photobioreactor, and (3) an integration of MBRs (aerobic MBR or anaerobic MBRs) with a membrane photobioreactor. For the second scenarios, a microalgae photobioreactor was used to treat the effluent of an anaerobic MBR for municipal wastewater treatment (Ruiz-Martinez et al. 2012). At a solid retention time of 2 days, the microalgae photobioreactor achieved a mean biomass productivity of 234 mg/d and a nutrient removal efficiency of 67.2 % for ammonium (NH_4^+-N) and 97.8 % for phosphate (PO_4^{3-}P) (Ruiz-Martinez et al. 2012). In the third scenarios, an aerobic MBR-membrane photobioreactor system was tested for domestic wastewater treatment (Singh and Thomas 2012). Similarly, a comparative study between the second and third scenarios found that the use of membrane photobioreactor significantly increased the microalgae biomass concentration and volumetric productivity by 3.5 and 2 times, respectively, in addition to the

elimination of microalgae washout and superior effluent quality (Marbelia et al. 2014). The membrane photobioreactor was able to remove an average 50 % of NH_4 , 75 % of NO_2 , 35 % of NO_3 , and 60 % of PO_4 consistently from the MBR effluent under the conditions tested (Marbelia et al. 2014). Integrated MBR-microalgae processes represent a next generation of technology for sustainable wastewater treatment.

Use of Streaming Potential Measurements for Characterization of Both Membrane/Electrolyte Interface and Protein Fouling Effect

Juana Benavente

Departamento de Física Aplicada I, Universidad de Malaga, Facultad de Ciencias, Malaga, Spain

Electrical nature of external and internal (pore-wall) membrane surfaces is significant for salt rejection and transport characterization of RO and NF membranes or for filtration of solutions containing macromolecules and colloids. Electrokinetic measurements are usually performed for characterization of membrane/electrolyte interfaces and to estimate changes associated to membrane fouling as a result of cake layer formation (external fouling) or pore narrowing/plugging (internal fouling).

Zeta potential (ζ) is the stationary electrical potential at the shear plane between fixed and mobile ions in the double layer associated to solid-liquid charged interfaces. For weakly charged walls or wide channels/pores, ζ -potential is obtained from streaming potential coefficient $(\Delta\phi_{st}/\Delta P)_{I=0}$ by Helmholtz-Smoluchowski equation (Hunter 1988):

$$\zeta_{H-S} = (\lambda_e \eta \epsilon_o \epsilon) (\Delta\phi_{st}/\Delta P)_{I=0} \quad (1)$$

where λ_e , η , ϵ , and ϵ_o are the solution conductivity, viscosity, membrane dielectric constant, and vacuum permeability, respectively.

To show the potentiality of electrokinetic characterization, ζ -potential results for clean and BSA-fouled porous membranes, polymeric (GR, polysulfone $\langle rp \rangle \sim 0.1 \mu m$) and ceramic (Z100S, ZrO_2/Al_2O_3 on stain steel support $\langle rp \rangle \sim 0.06 \mu m$), by transmembrane measurements at different pHs (Lara and Benavente 2009), and tangential measurements changing NaCl concentration for a dense regenerated cellulose (RC) membrane are presented (Cañas et al. 2001).

Figure 1a shows the comparison of ζ values as a function of solution pH for GR and Z100S membranes. Polysulfone GR membrane exhibits electronegative character, but it is electropositive

Use of Streaming Potential Measurements for Characterization of Both Membrane/Electrolyte Interface and Protein Fouling Effect, Fig. 1 ζ -potential as a function of (a) pH for clean (Δ) and BSA-fouled (▲) GM

membranes, clean (□) and BSA-fouled (■) Z100S membranes; (b) concentration for clean GM (Δ) and RC (◇) membranes

for ceramic Z100S; moreover, ζ -potentials for GR membrane slightly vary due to BSA fouling, but they significantly change for the ceramic sample (from positive to negative), and practically the same isoelectric point ($\zeta = 0$) was obtained with both fouled membranes, which corresponds to the BSA isoelectric point. These results indicate the BSA coverage of pore walls for both fouled samples.

Figure 1b shows ζ -potential dependence on solution concentration for clean GR (through pores) and dense RC (along surface) membranes, indicating absorption of Cl-ions on internal (GR) or external (RC) membrane surfaces.

Analysis of electrokinetic surface charge density or charge density at shear plane ($\sigma_e = (2RT\varepsilon_0\varepsilon \kappa/F)\sinh(F\zeta/2RT)$) with the molar fraction of ions ($c \approx C_n/M_{H_2O}$) can give information on adsorption parameters using adequate models (homogeneous Langmuir model or heterogeneous Freundlich model (Benavente et al. 1993), and the following values for the chemical part of free adsorption energy (ΔG_{ch}) and total number of adsorption sites per membrane area (N) were obtained for GR and RC membranes assuming a Langmuir model:

$$\text{Polysulfone GR: } \Delta G_{ch} = -(18.9 \pm 0.7) \text{ kJ/mol, } N = (4.9 \pm 0.4) \times 10^{15} \text{ m}^{-2}.$$

$$\text{Cellulosic RC: } \Delta G_{ch} = -(25.7 \pm 0.7) \text{ kJ/mol, } N = (1.4 \pm 0.5) \times 10^{16} \text{ m}^{-2}.$$

Differences associated to membrane material can be obtained; the negative sign and low values of ΔG_{ch} indicate spontaneous adsorption of Cl-ions on membrane pore-wall or external surface.

UV Irradiation

Jiahui Shao

School of Environmental Science and Engineering, Shanghai Jiao Tong University, Shanghai, China

UV radiation energy waves are the range of electromagnetic waves 100–400 nm long (between the X-ray and visible light spectrums), corresponding to photon energies from 3 to 124 eV. It is so named because the spectrum consists of electromagnetic waves with frequencies higher than those that humans identify as the color violet. The division of UV radiation may be classified as Vacuum UV (100–200 nm), UV-C (200–280 nm), UV-B (280–315 nm), and UV-A (315–400 nm). UV irradiation occupies only about 3–5 % of the total solar irradiance at the Earth's surface.

UV irradiation has many technical applications through the use of particular wavelength, including security, forensics, spectrophotometry, photolithography, sterilization, disinfecting drinking water, removing persistent organic compounds via photocatalyst, and initiating chemical reactions and others.

UV irradiation linked to membrane science and technology is manifested in three aspects.

1. UV irradiation for preparation, modification, and stimulation of polymeric membranes. For de novo preparation of membranes from low molar mass or soluble precursors, photo-initiated polymerization and photo

cross-linking are the main pathways, while photodegradation for pore formation is only rarely applied (He et al. 2009). For membrane modification, “grafting-from” and “grafting-to” are two commonly used strategies. The “grafting-from” method utilizes active species existing on a membrane surface to initiate the polymerization of monomers from the surface. For “grafting-to” method, polymer chains carrying reactive anchor groups at the end or on the side chains are covalently coupled to the membrane surface. Photostimulation of barrier properties is an attractive concept to create stimuli-responsive membranes and various ways to use photochromic moieties. Photoirradiation-based methods can be very versatile enabling technologies to improve the performance of polymeric membranes in technical separations (e.g., in gas separation, pervaporation, ultrafiltration, and microfiltration or as membrane adsorbers) and other processes (e.g., for controlled release or in sensor systems), and they will contribute to the development of entirely novel membrane-based materials (He et al. 2009).

2. The combination of photocatalysis utilizing UV irradiation with membrane separation, which is often called photocatalytic membrane reactors (PMRs). PMRs can be generally classified into two main configurations: (a) reactors with photocatalyst particles suspended in feed solution and (b) reactors with photocatalyst immobilized on/in the membrane. The major disadvantage of the configuration with photocatalyst in suspension is deterioration of the permeate flux and membrane fouling. PMRs with photocatalyst on/in membrane are

one solution for this problem. In this configuration, oxidation by hydroxyl radicals occurs on the external surface and within the pores of the membrane, while reactants are permeating in a one-pass flow. However, fixation of the photocatalyst often results in a loss of photoactivity and might cause destruction to the membrane structure (Mozia 2010).

3. UV irradiation for membrane fouling/biofouling control and membrane clean. UV irradiation integrated in membrane system is able to mitigate membrane biofouling, which is caused by deposition or growth of microorganisms on membrane causes. For the membrane with photocatalyst (such as TiO_2) on the surface or entrapped in, the fouling can be effectively controlled because the pollutants can be effectively degraded by the photocatalyst with UV irradiation during filtration process. The fouled membranes after membrane filtration can also be cleaned with only UV irradiation, which provides the photocatalyst-doped membrane self-cleaning property (Song 2012).

Vacuum Membrane Distillation (VMD)

Alessandra Criscuoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Vacuum membrane distillation (VMD) is one of the possible configurations of membrane distillation, where vacuum is applied at the distillate side in order to create the driving force for the water vapor and volatile transfer from the feed to the permeate side (Fig. 1).

The vacuum is achieved by means of a vacuum pump, and the distillate is recovered outside the membrane module in a refrigerated trap, where it condenses (at lab scale, liquid nitrogen is often used as condensing medium); see Fig. 2. As for the other membrane distillation configurations, membrane properties like pore size, porosity, and thickness affect the transmembrane flux, together with the temperature profile in the boundary layer of the liquid stream that makes the temperature at

the membrane surface (where the evaporation takes place) lower than that of the bulk. Nevertheless, it has to be pointed out that, in this case, the polarization phenomena occur only at the feed side, being the distillate one completely under vacuum. Moreover, the heat loss by conduction through the solid part of the membrane is negligible. For these reasons, the VMD is usually characterized by higher fluxes and energy efficiency than the other configurations. The high pressure difference established across the membrane could, however, increase the risk of membrane wetting.

Vacuum Membrane Distillation (VMD), Applications of

Alessandra Criscuoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Vacuum membrane distillation (VMD) can be applied to the treatment of aqueous streams for recovering purified water or for extracting specific volatile compounds. Concerning the first type of application, many studies have demonstrated the efficiency of the technique for liquid streams contaminated by nonvolatile species such as heavy metals or dyes discharged by textile companies (Criscuoli et al. 2008): in all cases, the distillate produced consists of purified water (able to be reutilized inside the productive plant or to be used for drinking/agriculture purposes) with rejection values generally higher than 99 %. Other positive performances are those related to the treatment of olive mill wastewaters (Garcia-Castello et al. 2010) and the recovery of fully demineralized water starting from brackish waters, seawaters, and reverse osmosis brines (Li and Sirkar 2005; Safavi and Mohammadi 2009; Méricq et al. 2011). In particular, for the application to salty solutions, two main benefits are claimed: the recovery of purified water and the production of a highly concentrated brine, with a consequent reduction of its volume and, therefore, of costs associated to its disposal. VMD can be

Vacuum Membrane Distillation (VMD), Applications of, Table 1 Main applications of VMD

Recovery of purified water from aqueous streams containing nonvolatile pollutants like heavy metals, dyes, etc.
Recovery of fully demineralized water from salty solutions and concentration of reverse osmosis brine
Concentration of fruit and vegetable juices
Recovery of volatile compounds like ethanol, ammonia, VOCs, etc., from aqueous solutions

also used for the concentration of fruit/vegetable juices (Al-Asheh et al. 2006; Zhao et al. 2008), again, with the aim of recovering water as distillate while producing a high concentrated retentate that can be easily stored and shipped.

Referring to the application of VMD to the extraction of specific volatile compounds contained in water streams, some examples are the removal of ethanol (Izquierdo-Gil and Jonsson 2003); the removal of ammonia (El Bourawi et al. 2007) or VOCs from water, like toluene, benzene, etc. (Couffin et al. 1998); and the recovery of aroma compounds (Soni et al. 2008; Diban et al. 2009).

Table 1 summarizes the main applications of VMD.

Vacuum-Driven Pervaporation

Alberto Figoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Pervaporation is a concentration-driven membrane process in which a feed liquid mixture is directly in contact with the “active selective layer” of the membrane, while the permeate in a vapor phase is constantly removed from the other side. The driving force is represented by a gradient in the partial vapor pressure that creates a chemical potential gradient in the liquid phase, which is

Vacuum-Driven Pervaporation, Fig. 1 Vacuum-driven pervaporation

responsible for the selective sorption of one feed component into the membrane matrix, its subsequent diffusion through the membrane, and its final desorption into the permeate side. In pervaporation, in order to maintain a vapor pressure difference, any of the following, i.e., a sweeping carrier gas, a vacuum downstream pressure, or a temperature difference, can be used. By applying vacuum to the downstream side, for instance, a decrease in the chemical potential gradient is obtained and a selective mass transfer can be induced (Vallieres and Favre 2004).

At small scale a vacuum pump is often used in order to get a low vapor pressure. At industrial scale, on the contrary, the dimensions required for a vacuum pump would be prohibitive to reach. An alternative is represented by the condensation of the permeate vapor that spontaneously creates a vacuum in the permeate side (Baker 2004) (Fig. 1).

Vacuum, as opposed to sweeping gas, does not require any further separation from the sweeping gas; moreover, the vapors can be recovered by condensation, and in many cases, its use can simplify the overall process.

Vapor Plasma Membrane Treatment

Stephanie Roualdes
IEM/UM II – CC 047, Place Eugene Bataillon,
Montpellier, France

Plasma processes (Yasuda 1985; d'Agostino 1990; Biederman and Osada 1992; Inagaki 1996) were initially developed for microelectronics in the 1950s. They represent a clean (producing few or not effluents) and also extremely flexible technology whose basic equipment, well adapted to automation, makes it possible to achieve goals as various as singular in terms of specific properties of use; their costs of operation are moreover relatively weak. Based on these advantages, they are used today in many fields of the materials chemistry (in particular the membranes field) even if their industrialization still remains not very developed, because of the high cost of the equipment necessary to their implementation and of a certain conservatism of the industrialists reticent to introduce this new technology, however so promising.

Defined by Crookes in 1879 as the fourth state of the matter, a plasma is a partially ionized and overall neutral medium generated by the application of an electric field to a gas phase at low pressure (<10 Torr). The energy of the applied electric field is transferred to free electrons which collide with the gas molecules. Such inelastic impacts make electrons achieve enough energy (up to 50 eV) to induce the ionization of gas molecules. Such ionized species (acquiring energies typically in the range of 0–2 eV) initiate a

high number of complex reactions (ionization, excitation, neutralization, recombination, deexcitation, etc.) constituting what is called a glow discharge. A glow discharge implies a high variety of species: electrons, negative and positive ions, radicals, neutral atoms and molecules, and also photons (emitted by radiative deexcitation) whose mixture constitutes the plasma state. A plasma is essentially characterized by its energy and its electronic density. Depending on the values of both microscopic parameters, different kinds of natural or artificial plasmas can be distinguished, being classified in two categories: hot plasmas and cold plasmas. Artificial plasmas, generated by a low frequency (25–450 kHz), radio frequency (1–500 MHz), or microwave (500 MHz–some GHz) continue or alternative discharge at rather low pressure (10–2–10 Torr), are cold plasmas. Cold plasmas are characterized by energy and electronic density equal to 1–10 eV and $1,010\text{ cm}^{-3}$, respectively. Their ionization degree is lower than 10^{-3} so that the gas phase is mainly made up of neutral species in an excited state (radicals). A characteristic of these plasmas is the absence of thermodynamic balance between the electronic temperature (several thousands of degrees) and that of gas (near to the ambient).

The interaction between a cold plasma and a material placed within it (substrate) results in several types of effects occurring simultaneously or consecutively. Four major effects are generally distinguished: plasma etching, plasma functionalization, plasma cross-linking, and/or formation of a deposit on the surface of the substrate (PECVD/plasma polymerization). The prevalence of one of these effects on the others is directly related to the nature of the gas subjected to the electric discharge. In the case of plasmas involving noncondensable gases (monoatomic or diatomic gases), the three principal effects are etching, functionalization, and cross-linking; the substrate undergoes surface modifications only. In the case of plasmas involving condensable gases (organic, inorganic, or organometallic compounds), the dominating effect is the formation, on the surface of the substrate, of a deposit made up of a three-dimensional matrix formed from fragments of the reagent gas combined in a random way. The

related plasma process is called plasma-enhanced chemical vapor deposition (PECVD) or plasma polymerization in the particular case of gases of organic compounds.

For details about plasma treatment applied to membrane materials, see the articles entitled “plasma etching,” “plasma functionalization,” “PECVD,” “plasma polymerization,” “plasma membrane,” and “plasma polymerized membrane.”

Variable Volume Diafiltration

Zoltán Kovács

Department of Food Engineering, Institute of Bioengineering and Process Engineering, Szent Istvan University, Budapest, Hungary

Variable volume diafiltration (VVD) is a type of batch diafiltration process in which fresh diluant is continuously added to the feed tank at a rate that is proportional but less than the permeate flow. This causes a gradually diminishing feed volume and a simultaneous concentration of macrosolute and removal of microsolutes. Thus, this technique is more than a simple diafiltration in its strict and traditional sense since it is not designed only to

wash out the microsolutes but also enables the concentration of the process liquor within a single-step operation.

The process is controlled by measuring the permeate flow and adjusting the diluant flow accordingly with a control valve. The proportionality factor α , that is, the ratio of diluant flow $d(t)$ to permeate flow $q(t)$, is then kept constant such that $0 < \alpha < 1$.

For a given process, in which the macrosolute concentration is to be increased from $c_1(0)$ to $c_1(t_f)$, while the microsolutes concentration is to be reduced from $c_2(0)$ to $c_2(t_f)$, the proportionality factor α can be calculated by the following formula (Tekić et al. 2002):

$$\alpha = \frac{R_1 \ln \frac{c_2(0)}{c_2(t_f)} + R_2 \ln \frac{c_1(t_f)}{c_1(0)}}{\ln \frac{c_1(t_f)}{c_1(0)} + \ln \frac{c_2(0)}{c_2(t_f)}}$$

where R_1 and R_2 are the rejection of macrosolute and microsolutes, respectively, and are assumed to be constants throughout the filtration process.

Variable volume diafiltration has been originally proposed by Jaffrin and Charrier (1994) for a UF/DF process for albumin production from human plasma. The proposed technique, however, has found to be suboptimal for that particular application as concluded by an in-depth mathematical analysis based on optimal control theory (Paulen et al. 2011).

Although variable volume diafiltration could offer substantial advantages over constant volume diafiltration in terms of water usage (Krstić et al. 2004), it compares unfavorably with an optimally run traditional diafiltration process (Foley 2006a). As a further improvement, Foley (2006b) has suggested that the performance of variable volume diafiltration under certain circumstances can be enhanced in terms of diluant consumption and operational time by including a pre-concentration step.

Variable volume diafiltration is a relatively new concept, and only a few experimental investigations on its performance are available in the literature. These include, for example, ethanol removal from albumin (Jaffrin and Charrier 1994), fructooligosaccharide separation

(Li et al. 2004), and whey desalination (Román et al. 2011).

and cross-flow velocity, respectively, in dead-end and cross-flow systems. However, shear rate can also be generated by moving the membrane surfaces instead of the surrounding fluid or by moving a mass very near to the membrane surface. This type of technique is categorized as dynamic filtration systems (DFSs), also called shear-enhanced filtration. A summary of the existing DFSs is given in Table 1.

Most DFSs decouple the generation of surface shear rate from the feed velocity. Thus in theory, the mechanical energy is more efficiently directed toward the membrane surface by membrane or liquid movement near the membrane surface. Ideally, these systems offer reduced energy consumption and more effective and efficient fouling minimization. Only a limited number of reports mention the weakness of DFS systems. General energy calculations in comparison to conventional dead-end or cross-flow systems are scarce, making it difficult to verify the claim of energy savings during operation compared to conventional membrane filtration systems. These systems also have other drawbacks, such as apparatus complexity, high tendency of the apparatus to breakdown at the moving parts, and a low packing density, leading to high costs per membrane area (Jaffrin 2008). The latter seems to be the main restriction to commercialize these technologies.

Vibrating membranes are categorized as DSFs. They are known as an effective technique to provide shear rate on the membrane-feed interface in order to control membrane fouling. It is relatively new and only few versions exist and have been tested for different applications, mainly for activated sludge filtration in membrane bioreactor (MBR) applications. The vibrating membranes include the vibrating hollow fiber modules (VHFM) and magnetically induced membrane vibrations (MMV). In the VHFM, the membrane module consists of hollow fiber membranes placed vertically. The skin layer is located at the outside of the fibers. The membrane modules are vibrated in a vertical motion at different frequencies (0–30 Hz) and different amplitudes (0.2–4 cm) (Beier et al. 2006; Genkin et al. 2006). The oscillation of

the membrane in a VHFM system can also be performed in the transverse direction, which also proved to maintain good performance. This technique has proven to significantly increase the

achievable fluxes both for yeast broth and activated sludge filtration (Beier and Jonsson 2007; Gomaa et al. 2011).

In MMV, the membrane (normally flat-sheet) is fixed onto a vibration frame that is directly connected to an engine. The engine vibrates the frame via a pull-and-push mode and the vibration is derived from a programmable sonic device (Bilad et al. 2012; Mezohegyi et al. 2012). Like in the DSF systems, only the liquid-membrane interface experiences shear stress and not the bulk liquid, thus minimizing energy consumption and limiting the impact of the movement on the bulk feed. The movement orientation of the vibrating parts faced the narrow face of the module in order to both prevent the bumping of liquid onto the membrane and minimize the associated energy dissipation.

VOC Recovery

Tadashi Uragami

Organization for Research and Development of Innovative Science and Technology (ORDIST), Kansai University, Suita, Osaka, Japan

Synonyms

Organic vapor recovery

Many industrial processes handling organic solvents emit volatile organic compounds (VOCs). These VOCs not only cause environmental pollution but also represent an economic loss. The VOC recovery has become a big issue that needs to be addressed. Traditional techniques for VOC removal include carbon adsorption, condensation, and absorption, and none is efficient enough to meet every need. Membrane separation has developed into an important technology for separating VOCs and other gaseous air pollutants from gas streams. The membrane technology utilizes a polymeric membrane that is more permeable to condensable organic vapors, such as C_3 hydrocarbons and aromatics, than it is to noncondensable gases such as methane, ethane, nitrogen, and hydrogen. Because the technology concentrates the VOC gas stream, it can be used with a condenser to recover the VOC. It is best suited for

relatively low-flow streams containing moderate VOC concentration (Fig. 1).

The typical overall VOC recovery process consists of two steps: (1) compression and condensation and (2) membrane separation. A mixture of vapor and air is compressed. The compressed mixture is cooled and condensed vapor is recovered. Uncondensed organics are separated from the gas stream and concentrated in the permeate by the membrane. The treated gas is vented from the system and the permeate is drawn back to the compressor inlet. The polymeric membrane consists of a layer of nonwoven fabric that serves as the substrate, a solvent-resistant microporous support layer for mechanical strength, and a thin-film selective layer that performs the separation. It is manufactured as flat sheet and is wrapped into a spiral-wound module. Membranes are best suited for treating VOC streams that contain more than 1,000 ppmv of organic vapor where recovered product has value. Typical VOC recovery using membrane separation ranges from 90 % to 99 % and can reduce the VOC content of the vented gas to 100 ppmv or less. In Table 1, VOCs that can be captured with the membrane separation technique are listed.

The separation of VOCs from nitrogen by composite hollow fiber membranes is reported. Microporous hollow fiber membranes were spun from poly(vinylidene fluoride) (PVF₂) using the phase inversion method, and the hollow fibers were coated with a thin layer of poly(ether block

amide) (PEBA), thereby forming composite membranes. PVF₂ was chosen as the substrate material because of its excellent thermal and chemical stabilities and good mechanical strength, and PEBA was selected as the active separating layer because of its good permselectivity and film forming properties. The membranes were tested for the recovery of representative VOCs including hexane, heptane, and cyclohexane, which are the main components of gasoline, and dimethyl carbonate, ethanol, methanol, and methyl *t*-butyl ether that are the oxygenates and octane number enhancers of gasoline. The separation of gasoline vapor from nitrogen was also investigated under various operating conditions (e.g., feed concentration, operating temperature). The PEBA/PVF₂ composite hollow fiber membranes were effective for the separation of hydrocarbon vapors from nitrogen.

PDMSvi was prepared from divinyl-terminated poly(dimethylsiloxane), platinum-divinyltetramethylsiloxane complex, oligosilylstyrene, and hexane. PDMSvi–Al₂O₃ composite hollow fiber membrane was developed by coating a PDMSvi-oligo film on the outer surface of an Al₂O₃ hollow fiber porous substrate. Microstructures of the composite membranes were examined using scanning electron microscopy (SEM), displaying a uniform PDMSvi-oligo coating layer, free of defects with a thickness of around 15 µm. Such composite hollow fiber membranes are suitable for VOC recovery from waste gas streams because of their high chemical stability. The separation performances of the

PDMSvi–Al₂O₃ composite hollow fiber membrane were studied using chloroform in N₂ as a test vapor mixture. By analyzing the experimental data obtained at various conditions with a mathematical model derived, the permeabilities of chloroform and nitrogen in the PDMSvi polymer membrane were obtained. The effects of temperature, feed flow rate, vacuum pressure on the permeate side, and feed concentration on the chloroform recovery were also investigated both experimentally and theoretically. A high chloroform recovery was recognized (Liu et al. 2005).

Volatile Organic Compounds (VOCs)

Tadashi Uragami

Organization for Research and Development of Innovative Science and Technology (ORDIST), Kansai University, Suita, Osaka, Japan

Volatile organic compounds (VOCs) are organic chemicals that have a high vapor pressure at ordinary, room-temperature conditions. Their high vapor pressure results from a low boiling point, which causes large numbers of molecules to evaporate or sublimate from the liquid or solid form of the compound and enter the surrounding air. Many VOCs are dangerous to human health or cause harm to the environment. VOCs are numerous, varied, and ubiquitous. They include both human-made and naturally occurring chemical compounds. VOCs play an important role in communication between plants. Volatile organic compounds (VOCs) are emitted as gases from certain solids or liquids. VOCs include a variety of chemicals, some of which may have short- and long-term adverse health effects. Concentrations

Table 1 Various volatile organic compounds

Compounds	bp (°C)	VOCs
Very volatile organic compounds (VVOC)	0 ~ 50–100	Propane, butane, methyl chloride etc.
Volatile organic compounds (VOC)	50–100 ~ 240–260	Formaldehyde, toluene, acetone, ethanol, isopropanol, etc.
Semivolatile organic compounds (SVOC)	240–260 ~ 380–400	Insecticide, plasticizer

The emitted VOCs have to be removed by any method. Membrane separation technology is effective for the removal of VOCs in air (see chapter ► [VOC recovery](#))

of many VOCs are consistently higher indoors (up to ten times higher) than outdoors. VOCs are emitted by a wide array of products numbering in the thousands. Examples include paints and lacquers, paint strippers, cleaning supplies, pesticides, building materials and furnishings, office equipment such as copiers and printers, correction fluids and carbonless copy paper, graphics and craft materials including glues and adhesives, permanent markers, and photographic solutions. Organic chemicals are widely used as ingredients in household products. Paints, varnishes, and wax all contain organic solvents, as do many cleaning, disinfecting, cosmetic, degreasing, and hobby products. Fuels are made up of organic chemicals. All of these products can release organic compounds while you are using them and, to some degree, when they are stored. Table 1 is listed some VOCs in WHO.

Volume Concentration Factor

Greg Foley
School of Biotechnology, Dublin City University,
Dublin, Ireland

The aim of any batch membrane filtration process is to reduce the retentate volume, thus increasing

the concentration of a key molecular or particulate species.

The volume concentration factor is simply the ratio of the initial solution volume to the final solution volume, i.e., V_0/V_f . It is usually denoted by the abbreviation VCF.

For a solute or particle that has a rejection coefficient of 1.0, the increase in concentration during batch operation is given by

$$c_f/c_0 = V_0/V_f$$

Therefore,

$$c_f = c_0 VCF$$

If the solute has an arbitrary and constant apparent rejection coefficient of σ , one gets

$$c_f = c_0 VCF^\sigma$$

Volume Index

Giuseppe Barbieri
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The use of membrane reactors has several advantages, the most important of which is related to the gain in terms of conversion, with better material exploitation and plant size reduction. In order to compare membrane performance with that of conventional operations, different parameters were proposed (Criscuoli and Drioli 2007).

Behind them, the volume index is a new index, introduced (Brunetti et al. 2007, 2011a, b, 2012a, b; Barbieri et al. 2011) as an important parameter when installing new plants, which must be characterized by low sizes and high productivities. In particular, it is an indicator comparing the membrane reactor (MR) volume with that of a

Volume Index, Fig. 1 Volume index as a function of feed pressure for an equimolecular $\text{H}_2\text{O}:\text{CO}$ mixture. Furnace temperature = 280 °C. Set CO conversion 90 % of the TREC (Brunetti et al. 2007)

traditional reactor (TR) one, in order to achieve a set conversion, Eq. 1:

$$\text{Volume Index} = \frac{\text{Volume}_{\text{reaction}}^{\text{MR}}}{\text{Volume}^{\text{TR}}}_{\text{Set Conversion}} \quad (1)$$

The volume index ranges from 0 to 1: a low volume index means that the reaction volume for a membrane reactor to reach the set conversion value is much lower with respect to that required by a conventional reactor. Therefore, the necessary catalyst weight in the membrane reactor is significantly reduced.

The water-gas shift reaction can be considered as an example:

The volume index is a decreasing function of CO feed pressure, at a set temperature (Fig. 1): when an equimolecular ($\text{H}_2\text{O}:\text{CO} = 50:50$) mixture is fed into the reactor at 1500 kPa and a final conversion of about 80 % (corresponding to 90 % of the *Traditional Reactor Equilibrium Conversion*) is considered, the MR volume is 25 % of that of a TR and the volume index is equal to 1/4. With a high feed pressure, more H_2 permeates through the membrane, causing the reaction to shift toward further CO conversion. As a consequence a lower catalyst amount is required to achieve a set conversion.

When the mixture is fed at 600 kPa, the reaction volume of the membrane reactor is 75 % of the traditional reactor one, for the same CO conversion.

Wash Water in Diafiltration

Greg Foley

School of Biotechnology, Dublin City University,
Dublin, Ireland

In the context of ► [diafiltration](#), wash water is simply another term for diluent.

This is the water used to replace impure solvent while retaining the desired product. A typical example might be the washing of a cell suspension prior to cell disruption to release an intracellular product.

The typical way of doing this would be to subject the cell suspension to batch crossflow microfiltration while adding wash water at a rate that exactly balances the filtrate (► [permeate](#)) flow rate. Thus, the cells are retained, but the impure liquid in which the cells are suspended is gradually displaced by wash water.

Water Competitive Diffusion

Siddhartha Moulik, B. Aakruthi Vaishnavi,
Harsha Nagar and S. Sridhar
Membrane Separations Group, Chemical
Engineering Division, CSIR-Indian Institute of
Chemical Technology, Hyderabad, India

Background: Increasingly stringent recycled water quality standards and environmental

regulations force industries to look out for attractive green technologies involving membranes. Appropriate selection and utilization of membrane process over a vast range of applications requires fundamental knowledge of transport mechanisms occurring within the membrane. To describe the transport mechanisms, several mathematical models have been developed that are divided into two categories: phenomenological and mechanistic models. In phenomenological model, the membrane is viewed as a “black box” through which the feed components pass selectively with a certain driving force, and the membrane performance is defined in terms of solute passage and water flux, whereas the concentrations in the feed and permeate sides are related by empirical equations. Mechanistic transport models relate the membrane performance to physical parameters such as pore structure, solute size, and chemical properties like mode and energy of interaction between the membrane and feed components. In dense membranes, the solution-diffusion and pore flow models are mostly followed. Depending upon the nature of feed components and quantity required to be separated, the membrane type is selected. Hydrophilic membranes are suitable for retaining organic component, whereas hydrophobic barriers are desirable for separating small amount of solvent from water.

Competitive sorption is a special characteristic taking birth from the relative hydrophilicity of the membrane. Due to the water-loving nature of the

membranes or owing to the repulsive force of the membranes to water other solutes, a layer of pure water gets adsorbed onto the membrane surface on the basis of size exclusion. Pervaporation, reverse osmosis, and forward osmosis are membrane processes wherein water sorption occurs along with ultrafiltration and microfiltration. The ion exchange membrane used in electrodialysis and the solid polymer electrolyte which conducts protons in fuel cell also undergo competitive water sorption.

Pervaporation (PV): Pervaporation is a unique membrane technique which has found considerable importance due to its efficiency in liquid mixture separation, which cannot be performed by conventional distillation processes. Examples include azeotropic mixtures, thermally unstable and thermally sensitive products, and mixtures possessing components with close boiling points (Sunitha et al. 2013). In this process a very small amount of feed solution is vaporized, using both polymeric and inorganic membranes resulting in low energy consumption. Membrane performance is based on the phenomena of preferential sorption which allows selective components to get preferentially sorbed on the membrane surface followed by diffusion through the pores and finally desorption on the permeate side as vapor. Depending on the hydrophilicity of the membrane, water from the solution gets sorbed on the membrane surface, preventing other solutes from permeating. Presently, inorganic membranes have been proven to be attractive alternatives since they have superior thermal resistance and mechanical strength as described by Sommer and Melin (2005). Kita et al. (1995), Kondo et al. (1997), and Li et al. (2001) separated the azeotropic mixture of tetrahydrofuran (THF)/water by using different types of zeolitic membranes, namely, A-type, Y-type, MOR, and ZSM-5. Gallego-Lizon et al. (2002) used polymeric, microporous silica and NaA-type zeolite for the dehydration of *t*-butanol/water mixtures obtained and reported high flux and selectivity values due to preferential sorption of water which competes against the corresponding organics for permeation.

$$\text{Process selectivity} = \frac{(X_{H_2O, perm}/X_{i, perm})}{(X_{H_2O, feed}/X_{i, feed})} \quad (1)$$

$X_{H_2O, Perm}$ = water concentration in permeate (wt. %)

$X_{H_2O, Feed}$ = water concentration in the feed (wt. %)

$X_{i, Perm}$ = concentration organic component in permeate (wt. %)

$X_{i, Feed}$ = concentration organic component in the feed (wt. %)

Electrodialysis (ED): ED is a process where water gets sorbed competitively to swell the ion exchange membrane and allow easy mobility of ionizable species. The principle of electrodialysis is displayed in Fig. 1a, and the experimental setup is illustrated in Fig. 1b. The laboratory setup of ED process is shown in Fig. 1c. In ED, water sorption allows transport of ionic moieties through the swollen portions of the membrane which promote conduction of both cations and anions retaining organic solvents and other solutes. Some examples include removal of sodium azide from DMSO/water mixtures to enable distillation which is otherwise not feasible in the presence the explosive azide (Ravikumar et al. 2013).

Figure 1a reveals the alternate arrangement of cation and anion exchange membranes for removal of ionizable species like salts, acids, and alkalis from aqueous solutions, while Fig. 1b provides illustration of a typical ED experimental setup wherein the ions move through a membrane stack which is subjected to DC voltage through electrodes on both sides. With time, the dilute gets depleted of ionizable compounds which get transferred to the concentrate compartments while a third solution is provided to rinse the electrodes, remove air gap, and collect by-products.

Membrane bioreactor (MBR): MBR comprises of a conventional activated sludge process coupled with membrane separation to retain the biomass effectively, producing a clarified and disinfected permeate water suitable for reuse. Significant benefits of MBR include complete

Water Competitive Diffusion, Fig. 1 (a). Principle of ED. (b). Experimental setup of ED

retention of particulate matter, high purity of dissolved organics, and stable operation performance. The water present in the effluent is able to pass through the pores of the membranes while most particulates and bacterial cells are retained in

the bioreactor which is linked to the pore size distribution of the membranes. The types of membranes used are different depending on the size of the contaminants of the treatment process. Typically, for contaminants with particle size ranging

Water Competitive Diffusion, Fig. 2 Aerobic MBR combined with RO for enhanced water purity

from 100 to 1,000 nm, MF membranes are used for removing suspended particles, UF for particle size of 5–100 nm excluding both bacteria and virus, and NF for particles with size 1–5 nm retaining bivalent and multivalent dissolved salts. The MBR design is of two types, where the membrane is either operated under direct pressure or vacuum. This can be done either by placing the membrane inside the tank in submerged mode or can be configured externally in sidestream mode of filtration. In submerged MBR system, the feed wastewater and the biomass are both passed through the membrane that is operated at a pressure lower than atmospheric, and a vacuum pump is used to draw the permeate out while the concentrated sludge is recycled back to the reactor. In the sidestream configuration, the membrane is placed in an external loop separated from the bioreactor, and a pump forces the biomass containing water under direct pressure in a cross-flow mode into the membrane module to generate permeate on the other with recycle of biomass to the reactor. Membrane filtration occurs either in aerobic or anaerobic configuration where oxygen acts as an important medium for biomass growth in the aerobic process while the anaerobic process is carried out in the absence of oxygen.

Aerobic membrane bioreactor: This type of MBR depends on aeration within the system

providing required oxygen transfer for growth of the biomass and mixing in the reactor. As shown in Fig. 2, the rising bubbles created by an air diffuser provide turbulent cross-flow over the surface of the membrane to maintain flux and reduce buildup of materials on the barrier, thereby increasing the operational cycle of the system.

Anaerobic membrane bioreactor: This process is operated without oxygen, and the anaerobic biomass degrades the particulate matter in the wastewater converting a part of it into biogas and using a membrane to provide complete solid-liquid separation.

With the advantage of biomass retention, these reactors are suitable to treat high-strength wastewaters and could also operate at higher COD/BOD loading rates (Germain et al. 2007). Figure 3 represents the anaerobic bioreactor where the membrane is immersed in a tank and operated under vacuum mode to withdraw permeate.

Forward osmosis (FO) and reverse osmosis (RO): Forward osmosis is a process which uses a semipermeable membrane for the transfer of water molecules due to the difference in osmotic pressure across the membrane allowing passage of water, rejecting solute molecules or ions. Some of the applications include sea- and brackish-water desalination and processing of

Water Competitive Diffusion, Fig. 3 Anaerobic MBR

pharmaceuticals besides concentration of fruit juices, dairy products, and beverages.

RO is a combination of interfacial phenomenon and fluid transport under pressure through capillary pores. In this process pure water is passed through a semipermeable membrane under the influence of hydrostatic pressure with simultaneous removal of impurities, organic contaminants, and salts. The two types of membranes used for reverse osmosis process are thin-film composite polyamide and cellulose acetate. Properties like water flux, rejection, and physiochemical characteristics are different for different membranes (Gullinkala et al. 2010). The thin-film composite (TFC) membrane has an upper ultra-thin active layer that mostly consists of cross-linked polyamide, polyester, polyurea, or polyetherurea which are supported on a porous polysulfone support with a grid of polyester fibers for mechanical stability at the bottom (Petersen 1993). TFCs exhibit high permselectivity to water and low resistance to mass transfer during osmotic flow due to the enhanced hydrophilicity nature. To evaluate RO system performance, water flux and % salt rejection of the membrane are determined experimentally. Water flux is measured as the volume (L) of permeate collected on a certain

period of time (h) per square meter per hour (m^2) of membrane area (L/m^2h) and calculated through the following equation:

$$J_v = \frac{Q}{AX\Delta t} \quad (2)$$

where J_v is the volumetric permeate water flux, A is the effective area of the membrane for permeation, and Q is the volume of permeation over a time interval Δt . Salt rejection is evaluated by the following equation:

$$\%R = \frac{C_f - C_p}{C_f} \times 100 \quad (3)$$

C_p and C_f are salt concentrations in permeate and feed, respectively. To understand the transport mechanism of RO process, different mathematical models are described which can be classified into three categories: (i) irreversible thermodynamics model/Kedem Katchalsky and Spiegler Kedem models; (ii) nonporous membrane models, viz., solution-diffusion, solution-diffusion-imperfection, and extended solution-diffusion models; and (iii) pore flow models like finely porous, preferential sorption-capillary flow

and surface force-pore flow models. Here, our focus is on the pore flow model.

Pore Flow Models

Preferential Sorption-Capillary Flow Model

This is a model proposed earlier by Sourirajan (1970) and is assumed that the mechanism of separation is carried out by both surface phenomena and fluid transport through pores in the RO membrane. As in the case of PV, as mentioned above, this model also assumes that chemical properties of the membrane attract the solvent and repel the solutes present in the feed solution. A layer of the pure solvent gets preferentially sorbed on the surface of the membrane and subsequently within the pores of the membrane. Solvent transport is forced through the capillary-like pores under pressure. According to this model the water flux is given by

$$N_w = A[\Delta P - \{\pi(X_F) - \pi(X_P)\}] \quad (4)$$

where A is the pure water permeability constant of the membrane, and $\pi(X)$ represents the osmotic pressure of the feed with solute mole fraction X .

The solute flux is expressed as

$$N_s = \frac{D_{SP}K_D C_T}{\delta} (X_F - X_P) \quad (5)$$

where K_D is the distribution coefficient of the solute between the feed and the pores of the membrane, and D_{SP} is the diffusivity of the solute within the membrane pore. Solute rejection is given by

$$\frac{1}{R} = 1 + \frac{D_{SP}K_D C_T}{\delta} \times \frac{1}{A[\Delta P - \{\pi(X_F) - \pi(X_P)\}]} \quad (6)$$

These equations were used to analyze transport for a large number of solutes and membranes by Sourirajan and Matsuura (1985). But the drop in water flux and solute rejection caused by presence of dilute organics is not adequately described by these equations.

The surface of the membrane in contact with the solution has a preferential affinity for water and repulsion toward the solute. According to the capillary flow model, solutes move through the membrane by solution-diffusion, advection, or both (Chanda and Roy 2008). Figure 4 shows

Water Competitive Diffusion, Fig. 4 Phenomenon of competitive water sorption in RO

the detailed mechanism of water competitive sorption in RO process. This separation process is a function of surface chemistry of the membrane as well as the way water is transported through the membrane. The solutes having higher hydration radii will be rejected by the adsorbed water, but other smaller solute molecules can diffuse through the membrane pores.

Compounds which exist as cations, anions, or zwitterions, depending upon the solution pH, can be separated by a unique mechanism from fermentation broths. Ion exchange membranes are modified hydrophobic polymers which contain small volume unsuitable for separation of large organic molecules besides possessing inherent disadvantages like high energy consumption, organic fouling, etc.

To minimize these problems, ion exchange membranes having high proton conductivity, low electrical resistance, high water sorption, and permselectivity are prepared. Swelling property

of these membranes has been investigated with different solvent-water mixtures containing ionizable solutes. Therefore, Kang et al. (2002) prepared a cation exchange membrane which had a high water-swelling property with significant conductivity and low electric resistance, which was poly(vinyl alcohol) (PVA)/poly(styrene sulfonic acid-co-maleic acid) (PSSA-MA) for separation of large molecular cations of amino acids. The electric resistance of the PVA/PSSA-MA membrane is lower than commercial membranes for easier transport of large molecular cations due to the relatively higher free volume present in the membrane structure. As a result, PVA/PSSA-MA membranes show better separation efficiency in the presence of water since their permeable matrix allows the large cation molecule to easily pass through the negatively charged barrier. Table 1 represents the literature review of processes involving water competitive sorption.

Water Competitive Diffusion, Fig. 5 Principle of fuel cell

Fuel cell (FC): Fuel cell is used for safe, pollution-free, and eco-friendly conversion of chemical energy into electrical energy through redox reaction. The membrane-based fuel cells are PEMFC and DMFC with the structure of fuel cell containing two electrodes, anode and cathode, separated by a gas-tight, proton-conducting membrane which is called as the membrane electrode assembly (MEA). The oxidation reaction that occurs in the anode produces electrons which move through the external circuit and protons that migrate from anode to cathode side through the membrane. In this process the hydration state of the membrane plays an important role as shown in Fig. 5.

At molecular level, the proton transport phenomenon occurs by two major mechanisms, i.e., jumping or Grotthuss mechanism, wherein the produced proton gets exchanged with the adjacent proton present in the sulfonic acid clusters of the solid polymer and continues until the proton reaches the cathode to complete the reaction. Thus, in the jumping mechanism the protons hop from one hydrolyzed ionic site ($\text{SO}_3^- \text{H}_3\text{O}^+$) to another across the membrane as shown in Fig. 6a.

In this mechanism, the hydrated regions are distributed randomly in the polymer matrix, which facilitates quicker transport of protons by rotation of the side chains. The ionic clusters swell in the presence of water, and proton transfer occurs through percolation mechanism. The second mechanism is vehicular mechanism, where the hydrated protons (H_3O^+) diffuse through the aqueous medium in response to the electrochemical difference and the hydronium ion ($\text{H}^+ (\text{H}_2\text{O})_x$) as a result of the electroosmotic drag carries one or more molecules of water through the membrane as shown in Fig. 6b. In DMFCs methanol permeates the membranes primarily through ionic channels, and thus the cross-sectional size of these channels influences permeability. This size is largely dependent upon the extent of membrane swelling which facilitates the permeation of both methanol and water as well as that of protons. The swelling-induced disentanglement behavior in polymer matrix is significantly responsible for the enlargement of the ionic channels and consequently for increasing methanol crossover. Hence, maintaining a high water content in the electrolyte is essential to ensure high ionic conductivity.

Water Competitive Diffusion, Fig. 6 Schematic of (a) jumping/Grotthus mechanism and (b) vehicular mechanism

Table 2 represents sorption data of fuel cell membranes. Synthetic zeolite membranes have been attractive than polymeric membranes for the recovery of polar solvents like dimethylformamide (DMF), dimethyl sulfoxide (DMSO), dimethylacetamide (DMAC), N-methyl-2-pyrrolidone (NMP), tetrahydrofuran (THF), etc. They are used in different separation processes such as pervaporation, ultrafiltration, and microfiltration. The structure of zeolite is of crystalline order and, due to its narrow size pore

distribution, provides resistance toward different solvents besides stability at high temperatures.

Transport of water through the zeolite matrix comprises of three steps: (i) strong adsorption of species in the zeolite cage, (ii) surface diffusion of the species occurs from cage to cage, and (iii) vaporization of species on permeate side. In pervaporation, different mixtures such as THF/water are separated using specific types of zeolitic membranes, viz., A-type, Y-type, MOR, and ZSM-5 (Li et al. 2001). Zeolite membranes

Water Demineralization

Daphne Hermosilla, Carlos Negro and
Ángeles Blanco

Department of Chemical Engineering,
Universidad Complutense de Madrid, Madrid,
Spain

Demineralization consists of removing dissolved minerals (salts, ions) from water. In fact, the large variety of existing applications for demineralized water, such as the production of potable water or its use in diverse industrial processes (e.g., electrical components production and pharmaceutical industry), among others, has particularly contributed to the actual high degree of development of membrane processes (Wang et al. 2011).

There are many demineralization technologies. They may be classified considering the main driving force used to remove ions. Membrane technologies, such as reverse osmosis (RO) and nanofiltration (NF), are those in which the main driving force is pressure; others set an electrical gradient as its driving force, such as capacitive deionization, electrodialysis, and electro-deionization, or a temperature gradient, such as distillation; and others use a chemical driving force such as ion exchange. There are also hybrid processes, mainly those including membranes to improve the efficiency of the separation process, such as thermal-membrane technologies (e.g., membrane distillation).

Proven technologies including membranes or their combination with other processes are numerous, and the mechanisms to achieve demineralization vary from each other; pressure-driven membrane demineralization technologies are mainly based on size separation, ionic charge, and diffusion, as in RO and NF. Particularly, NF is useful for reducing salt content in water, mainly of the size of bivalent ions (Ca^{2+} , Mg^{2+} , SO_4^{2-} , CO_3^{2-}), due to its 0.5–2 nm pore-size filtration range, for which a 3–20 bar pressure is necessary, but it is not able to totally reduce the mineral content. On the other hand, RO may separate

lower molecular mass compounds ($>1\text{--}0.1\text{ nm}$), mainly by diffusion, achieving the successful removal of monovalent ions (as high as a 98 % salt rejection, including Na^+ , K^+ , Cl^- , NO_3^{3-} , etc.) but increasing the required pressure for separation (5–120 bar) (Ordoñez et al. 2014; Wang et al. 2011), therefore increasing the consumption of energy as well.

The main advantages of these technologies are their technological maturity, which makes them profitable and available for numerous applications; and its total success in separating both the inorganic and organic fractions, which are not able to pass through the membranes, hence achieving not only the removal of the major part of organic and inorganic compounds in water but also disinfection, especially when a double-membrane system is used. RO process is currently the fastest growing technique for seawater and brackish water desalination, being definitely the most applied one (60 % of the world's desalination capacity), followed by distillation (34.8 %), electrodialysis (3.6 %), hybrid processes (0.8 %), electro-deionization (0.3 %), and others (0.3 %) (IDA 2011). On the other hand, preventing bio-fouling and scaling, which is directly associated with energy consumption, and the management of concentrated brines are the main challenges for these technologies to overcome.

Among electrical current-driven processes including membranes to improve demineralization, electrodialysis (ED) is the most commonly applied one. This process uses ionic exchange membranes, cationic and anionic, located in parallel separating compartments and placed between electrodes in order to separate demineralized water from concentrated water setting an electrical gradient across membrane compartments. The reverse ED process is very similar, but its cathodes and anodes can be reversed for cleaning purposes, so scaling trouble is reduced. The size of ionic solutes to be rejected or separated by ED is normally in the range of 0.00025–0.08 mm, depending on the pore size of ED membranes (Wang et al. 2011). This process cannot disinfect water as non-charged particles are not separated. Moreover, the final salt concentration is usually higher than when RO systems are applied. On the

other hand, it is a robust process that may deal with a high variety of influent water qualities. Electro-deionization is based on the same principles, but it uses ionic exchange resins to improve desalination efficiency retaining ions, therefore improving further desalination by ionic exchange membranes, thus reducing power consumption as well (Lee et al. 2013).

On the other hand, capacitive deionization is a technology that is attracting much interest, and it is currently being developed for industrial applications. It is also based on applying an electrical driving force to absorb ions onto the surface of porous electrodes that may temporarily store them, thanks to the double layer that is formed within the electrode-water interface, and the demineralized water flows into the spacer compartment. The electrodes must be regenerated when they are saturated with ions, which can be achieved by reversing polarity. This treatment may be improved by introducing ionic exchange membranes in parallel to the electrodes (membrane capacitive deionization) because they improve the retention of ions and make cleaning easier by reversing polarity (Biesheuvel and Van der Wal 2010).

Thermal treatment technologies, such as distillation, have been used to demineralize water for many years, and although distillation is the second largest technology worldwide applied for desalination, it is nowadays being replaced by RO, thanks to its versatility and lower associated costs (energy consumption, mainly). Among thermal technologies including membranes to improve separation, there are mainly two technologies that are nowadays under strong development: pervaporation and membrane distillation.

Pervaporation is a new process under development that is nowadays being introduced at an industrial scale. It is a partial pressure-driven process in which transport through the membrane is induced by the vapor pressure difference that is hold between feed and permeate vapors. Feed water is put in contact with one side of a membrane, and the permeate is removed as a low pressure vapor on the other side. This process is based on sorption and diffusion differences between water characteristics, membrane

materials, and the properties of the permeate (Baker 2004; Wang et al. 2011).

Membrane distillation combines membrane technologies with distillation processes. The water to be demineralized is first warmed up to produce a vapor that can pass through the membrane. This vapor is condensed in a cooler surface to produce the treated water, which is not able to pass across the membrane. Their main advantage is its simplicity and the low temperature gradient that is required to perform this operation. However, when the process is run applying low temperature differentials, large amounts of water must be used, which affects its overall energy efficiency. This technology is currently being under development, and different improvements are being tested, such as the use of solar energy (Ding et al. 2005).

All these technologies must deal with two main problems: fouling and scaling and the production of brines, which must be properly managed. In order to deal with fouling and scaling phenomena, feed water is usually pretreated by different technologies first, such as filtration, chemical coagulation, flocculation, or softening (Wang et al. 2011).

Water Deoxygenation by Catalytic Membranes

V. V. Volkov

A.V. Topchiev Institute of Petrochemical Synthesis Russian Academy of Sciences (TIPS RAS), Moscow, Russian Federation

The process of catalytic removal of dissolved oxygen (DO) from water presents an encouraging example for the industrial application of palladium catalysts supported on ion-exchange resins. Noteworthy is that the existing catalytic processes for deoxygenation of water via hydrogenation reaction involve two stages: (1) absorption of hydrogen in water and (2) passage of water containing dissolved hydrogen and DO through a fixed-bed catalytic reactor.

Catalytic membranes, i.e., palladium-loaded hollow fibers, can be prepared by deposition of palladium nanoparticles onto an outer surface of the hydrophobic porous polypropylene (PP) hollow fiber membranes and allow the DO removal from water in one stage (van der Vaart et al. 2001).

The principle of DO removal using a catalytic membrane is illustrated in Fig. 1. The hydrophobic porous catalytic membrane serves three key functions: (1) a well-defined and easily controlled location of a hydrogen–water interface, (2) accessibility of a catalyst for reagents (hydrogen and oxygen), and (3) high overall mass transfer coefficient. DO-containing water flows over the outer surface of the Pd-loaded hydrophobic hollow fiber membrane, whereas hydrogen, as a reducing agent, is supplied into the lumen side of hollow fibers and approaches the working surface of a catalyst through the pores of the membranes. Due to the catalytic activation of hydrogen adsorbed on the palladium surface, a heterogeneous reaction of DO reduction takes place. Consequently, this design allows good access of both the gas phase and liquid phase reactants to the catalyst placed on the outer membrane surface, and this system is well suited for hydrogenation reactions in aqueous media. Moreover, the reaction proceeds at room temperature. The process of water deoxygenation based on catalytic

Water Deoxygenation by Catalytic Membranes, Fig. 1 A scheme illustrating the process of DO removal from water using a Pd-loaded porous hollow fiber membrane: 1 deposited Pd, 2 polypropylene porous support (Volkov et al. 2011)

membranes is capable of achieving residual oxygen concentration below 10 ppb.

Water Desalination in Electrodialysis Applications

Hacene Mahmoudi

Science and Technology, Faculty of Technology, University Hassiba Benbouali of Chlef, Chlef, Algeria

Desalination is a process that removes dissolved minerals from seawater or brackish water. About

71 % of the earth surface is covered by water which is in the form of the oceans, the seas, and the ices in the poles. However, only 2.5 % of water is fresh and suitable for drinking. Therefore, some special processes are needed to desalinate these waters. Presently, the world's total desalination capacity is around 60 million m³/day and will reach around hundred millions m³/day by 2015. 63.6 % of the total capacity is produced by membrane processes and 34.8 % by thermal processes (Drouiche et al. 2011). Among the membrane techniques, electrodialysis which is a process based on the transport of ions through selective membranes under the influence of an electrical field. Electrodialysis (ED) is an electrically driven process in which mineral salts and other species are transported through ion selective membranes from one solution into another under the driving force of direct electrical potential. Salts are in solution as ionized particles with positive and negative charges. When direct current is imposed on the solution, the positive ions migrate to the negative electrode, or cathode, and the negative ions migrate to the positive electrode, or anode (see Fig. 1) (Takashi 2007).

During the last 60 years, electrodialysis was used on a large industrial scale for the production of freshwater from brackish water. This technique is considered as reliable and inexpensive process and has proved its feasibility and high performance in the desalination of brackish water (Korngold et al. 1978). It is now well established that electrodialysis, when applied for certain range of feed water salt composition, has many advantages compared to other desalination processes (mainly reverse osmosis). In fact, electrodialysis is well suited for small to medium size plants with capacities ranging from 100 m³.d⁻¹ to 20,000 m³.d⁻¹ and feed water salinity from 1 to 5 g.L⁻¹ total dissolved solids (TDS). When the TDS exceeds 10 g.L⁻¹, reverse osmosis presents better economic advantages compared to electrodialysis. The latter, when considered for brackish water desalination, presents high water recovery rates and long membrane life and can operate at high temperature up to 50 °C. Also, the modification of the ED

Water Desalination in Electrodialysis

Applications,
Fig. 1 Charge transport in a conventional electrodialysis system

process in which the polarity of the applied voltage is (EDR) changed periodically, reversing the direction of ion movement. The process is known as electrodialysis reversal (EDR) and can dramatically decrease the membrane fouling or scaling. On the other hand, electrodialysis does not remove colloidal particles, matter that is not ionized and presents serious limitations when treating feed water charged with neutral toxic components such as viruses or bacteria (Strathmann 2010).

The current International Desalting Association World Desalting Plants Inventory shows that 13.7 % of the brackish water desalting capacity in the world is ED and EDR.

Water Disinfection by Membrane Operations

Yvan Wyart

CNRS, Centrale Marseille, M2P2 UMR 7340, Equipe Procédés Membranaires (EPM), Aix Marseille Université, Aix en Provence Cedex, France

Nowadays, more and more drinking water are produced by membrane technology, especially from fresh water using microfiltration or ultrafiltration. That can be explained by the fact that ultrafiltration membranes exhibit a high or even complete level of viruses, bacteria, and protozoa cysts (*Giardia* and *Cryptosporidium*) removal.

However, membranes and membrane modules can be damaged during water production, causing a loss of membrane system integrity and leading to the passage of pathogens through membranes and the contamination of filtered water. Thus, accurate and efficient integrity tests of membrane systems are necessary to guarantee the quality of filtered water. That is why a lot a research were carried out to develop the best membrane integrity test. Among them, direct and indirect membrane integrity tests can be distinguished.

Direct membrane integrity tests are directly applied to membranes or membrane modules. In this category, pressure decay test (PDT) and

diffusive air flow (DAF) test can be cited (Adham et al. 1995; Johnson 1998). Such tests characterize directly membranes or membrane modules structure to evaluate the pathogens removal, but they are conducted off-line. Indirect membrane integrity tests characterize filtered water quality parameters to evaluate the ability of membranes or membrane modules to remove pathogens. Particle counting (Panglisch et al. 1998) and turbidity monitoring (Banerjee et al. 2001) are indirect membrane integrity tests. They can be conducted on-line, but they are not able to detect water quality changes at the levels required to ensure pathogen removal. Among these tests, PDT and DAF test are the most frequently used tests in drinking water production due to their advantages of simplicity, low maintenance, reliability, and high sensitivity to detect membrane breaches.

Among the last developments in membrane integrity field, except Phattaranawik et al. (2008) who proposed a new membrane integrity test based on monitoring relative transmembrane pressure created by two intact membranes in series, all the other developments were focused on the characterization of filtered water quality: microbial challenge test (Brehant et al. 2010), nanoscale probe challenge test (Gitis et al. 2006), and magnetic nanoparticle challenge test (Guo et al. 2011).

The sensitivity of the membrane integrity test is an important factor to be considered. This parameter is a relevant indicator to guarantee the pathogen removal credit. Generally, the sensitivity of membrane integrity tests is expressed in terms of log removal value (LRV) of pathogens in drinking water. PDT and DAF test are able to detect membrane integrity at high levels of 5–6 LRV, even more than 6 LRV for DAF test.

The frequency of the membrane integrity test is important in order to maintain specific LRV requirements. There are no common guidelines for the frequency of membrane integrity tests. Membrane integrity test frequency needs to be related to a risk assessment as the first priority and operational practicality as the second priority. In the case of hollow fiber membranes, the frequency of membrane integrity test can be calculated, given an expected number of fiber breaks per year and a LRV target (Bennett 2005).

Today, the perfect integrity test has not been found. Thus, it remains essential to develop an alternative on-line monitoring test to better satisfy regulatory requirements for drinking water industry. This “ideal” test should be quick, sensitive, accurate, simple, continuous, and relatively inexpensive to be developed at industrial scale.

Water Electrooxidation

Marc Cretin

Institut Européen des Membranes, ENSCM-UM-CNRS (UMR 5635), Université de Montpellier, Montpellier Cedex 5, France

National School of Chemistry of Montpellier, University of Montpellier, Montpellier, France

By using a high O₂ evolution overpotential anode, water electrooxidation can be considered as an indirect anodic oxidation process. It can be

classified as an electrochemical advanced oxidation process (EAOP) because it leads to the in situ production of the hydroxyl radical ($\cdot\text{OH}$), the second powerful oxidant (after fluorine) with $E^0(\cdot\text{OH}/\text{OH}^-) = 2.80\text{V}/\text{SHE}$. Hydroxyl radical is a very reactive species (Brillas et al. 2009; Oturan and Aaron 2014) able to mineralize any organic pollutant. Therefore, this indirect anodic oxidation process is used in order for destruction of bio-refractory pollutants.

In this process (Panizza and Cerisola 2009), $\cdot\text{OH}$ s are produced at anode surface from water oxidation using a high O_2 evolution overpotential anode such as boron-doped diamond (BDD) electrode, from the following electrochemical reaction:

where M represents the anode material and $\text{M}(\cdot\text{OH})$ hydroxyl radical adsorbed on the anode.

Pollutants (R) are then oxidized as follows:

Under polarization, an undesirable reaction is water oxidation to dioxygen (called oxygen evolution reaction):

When oxygen evolution reaction is concomitant with hydroxyl radical formation, it leads to radical desorption:

The rate of this secondary reaction depends on the anode material and the applied potential. Table 1 gives the potential for oxygen evolution reaction (OER) on different anodes in different conditions.

It can be then distinguished as anodes with good catalytic properties for OER (i.e., low oxygen evolution overpotential, DSA (dimensionally stable anode), RuO_2 , IrO_2 , Pt, and graphite) to anodes with poor catalytic properties for OER (i.e., high oxygen evolution overpotential, SnO_2 , PbO_2 , and BDD). Those two types of anode are

Water Electrooxidation, Table 1 Potential for oxygen evolution reaction (OER) on different anodes in H_2SO_4 . Standard potential for OER is 1.23 V versus SHE

Anode	Value versus SHE	Conditions
RuO_2	1.47	0.5 M H_2SO_4
IrO_2	1.52	0.5 M H_2SO_4
Pt	1.6	0.5 M H_2SO_4
OPG ^a	1.7	0.5 M H_2SO_4
SnO_2	1.9	0.05 M H_2SO_4
PbO_2	1.9	1 M H_2SO_4
BDD	2.3	0.5 M H_2SO_4

^aOPG oriented pyrolytic graphite

currently proposed (Comninellis 1994) to describe indirect anodic oxidation and called “active” and “nonactive” anodes.

Whatever is the type of anode (schematized MO_x), the first step of the process is the oxygen transfer reaction (discharge of water molecule) to form adsorbed hydroxyl radicals:

The following steps can be distinguished for “active” and “nonactive” anodes.

At “active” electrodes, higher oxidation states of the material are possible, and then, the production and adsorption of $\cdot\text{OH}$ form a higher oxide:

A redox couple $\text{MO}_{x+1}/\text{MO}_x$ called “chemisorbed active oxygen” is then formed at the electrode surface and can be engaged in a selective and partial oxidation of the pollutant R:

At “nonactive” electrodes, hydroxyl radicals are physisorbed as “active oxygen” because of the stability of the electrode surface and can act for the nonselective and total oxidation of the pollutant R to CO_2 :

Hence, it is possible to combine indirect anodic oxidation at the anode with the electro-Fenton

process in bulk (by using a carbonaceous cathode) to get a high mineralization rate of pollutants. In this case, $\cdot\text{OH}$ is formed simultaneously at the anode as well as in the bulk solution from the electro-Fenton reaction at the cathode; the oxidation power and mineralization efficiency of persistent organic pollutants are then extremely high (Dirany et al. 2010).

Water Gas Shift (WGS)

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In the last decades, great attention has been paid to hydrogen as a carrier to be used for the production of clean energy by means of new technologies, designed to enhance efficiency and environmental sustainability, especially for power generation. Hydrogen is also utilized in a large amount in the chemical and petrochemical industry for ammonia synthesis, hydrocracking, hydrotreating, etc. Currently, hydrogen is mainly produced from fossil fuels (96 %): the stream coming out from a reformer or a coal gasification plant contains about 50 % H_2 that

has to be recovered and 40–45 % CO which can be utilized for producing more hydrogen. Thus, an upgrading stage is required, and the water gas shift (WGS) reaction is the most feasible one for this purpose. The water gas shift reaction is

Low temperatures thermodynamically favors CO conversion, but pressure (in a traditional reactor) does not affect it since the reaction is exothermic and characterized by no variation of the mole number.

Kinetics is promoted by a high temperature and slightly depends on the feed pressure.

WGS process is conventionally operated in two fixed-bed adiabatic reactors, in series, with a cooler interposed between them. So the WGS traditional process consists of:

1. A first reactor operating at high temperatures (300–450 °C) and GHSV (20,000 h^{-1} , gas hourly space velocity), using $\text{Fe}_2\text{O}_3\text{-Cr}_2\text{O}_3$ catalyst (Bustamante et al. 2004; Keiski et al. 1996; Ullman's Encyclopedia of Industrial Chemistry & 5th Completely Revised Edition 1995) which shows high kinetic activity when operated at a temperature higher than 300 °C. Taking advantage of the high reaction rate, this reactor converts the most of CO .
2. A heat exchanger for cooling the stream from 400–450 °C down to 200 °C ca.
3. A second reactor operating at lower temperatures (210–300 °C) and GHSV (2,000 h^{-1}) for reducing the CO fraction in the gaseous stream to less than 1 %. This reactor uses CuO-ZnO - (Bustamante et al. 2004; Ullmann's Encyclopedia of Industrial Chemistry & 5th Completely Revised Edition 1995; Amadeo and Laborde 1995) or CuO-CeO_2 -based catalysts and takes advantage of the low temperatures displacing the equilibrium, since the exothermic character of the WGS reaction.

$\text{H}_2\text{O}/\text{CO}$ feed molar ratio typically ranges from 2 to 5 for shifting the thermodynamic equilibrium

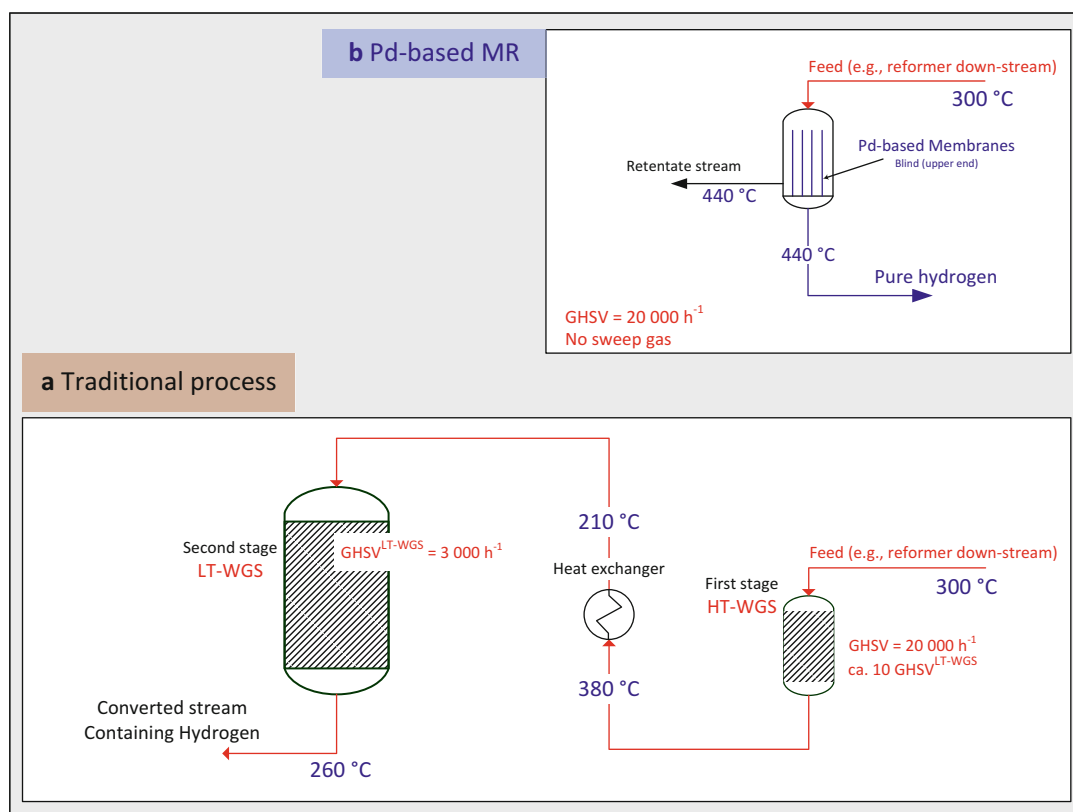

conversion and increases the reaction rate and thus hydrogen yield. The WGS is often followed by a further step of remaining CO elimination since CO is a poison for many industrial catalysts. Thus, this H₂-rich stream is usually directed to a CO selective/preferential oxidation reactor and then to a pressure swing adsorption unit for separating H₂ from the other gases.

For providing a better exploitation of raw materials together with the reduction of the reaction/separation/purification stages and related loads, the use of membrane reactors (MRs) is a promising approach, as they combine the reaction and the H₂ separation by means of a selective membrane (Brunetti et al. 2012a; Shu et al. 1991; Uemiya et al. 1991; Dittmeyer et al. 2001; Brunetti et al. 2012b).

The presence of the membrane allows the recovery of a hydrogen-rich/pure stream which

does not require any additional separation. Moreover, the removal of the hydrogen, which is a product, from the reaction volume shifts the reaction toward a further conversion.

The removal of hydrogen by a membrane gives many advantages: the reverse reaction rate is depleted owing to the lower H₂ concentration; the residence time of reactants is increased; the thermodynamic equilibrium of a membrane reactor exceeds that of a traditional reactor; the pressure has a positive effect on conversion in a membrane reactor, even if no variation in the number of mole is involved in the WGS reaction (Marigliano et al. 2003). Therefore, the use of a membrane reactor allows obtaining a higher conversion also at higher temperature where the thermodynamic conversion is low, acting positively on the kinetics. Consequently, the amount of catalyst necessary for a given conversion can be

Water Gas Shift (WGS), Fig. 1 Schemes of “Pd-based membrane reactor” and “traditional process” for WGS reaction (Marigliano et al. 2003)

significantly reduced (Barbieri et al. 2011). In fact, one membrane reactor operating at high temperature was demonstrated replacing the two reactors of the traditional process (Fig. 1), giving the same final conversion or higher.

Among the several membrane types, the Pd-alloy membranes are the most used for the selective removal of hydrogen in applications such as dehydrogenation reactions, thanks to their infinite H₂ selectivity. An important aspect in the use of Pd-alloy MR is the good exploitation of whole the available membrane area, which allows the improvement of the global performance, with higher CO conversion and more H₂ recovered in the permeate side (Barbieri et al. 2008).

Currently, self-supported Pd-Ag membranes are produced at commercial level, and, when used to investigate experimentally the WGS reaction at a laboratory scale, they showed a high durability and performance stability for more than 2 years operating at 330 °C and up to 10 bar (Barbieri et al. 2008).

The results obtained at a laboratory scale concretized in some cases in various patents. For example, United Technologies Corp. patented the use of a WGS MR, comprising a WGS reaction region a permeate volume, separated by an H₂-separation membrane which allows H₂ formed over a catalyst in the reaction region to be passed selectively to the permeate region (Gummalla et al. 2010).

Water Purification

Davide Mattia

Department of Chemical Engineering, University of Bath, Bath, UK

Water purification refers to the production of potable water from a variety of sources, including groundwater; surface sources like lakes, rivers, sea, or brackish water; artificial reservoirs; and sewage treatment plants. The first three sources are linked together in the so-called water cycle, where moisture present in the atmosphere

condenses, generating precipitation; in turn, this reaches the ground, vegetation, and other surfaces. Part of this water evaporates back in the atmosphere, while another fraction infiltrates the ground, replenishing groundwater reservoirs as well as supplying natural (and artificial) water bodies. Human activity interferes with this natural cycle abstracting water from ground and surface sources and adding pollutants, solids, and contaminants to it. Modern water management includes treating waste streams produced by human activity as well as producing potable water from saline sources and creating artificial surface reservoirs.

Rainwater is not pure but contains dissolved gases, particulate, and bacteria picked up during its fall. Therefore, it is not pure water but it is very *soft*. Surface water, washing over soil and other surfaces, carries with it any mobile or dissolvable substance, including bacteria, soil, and vegetation. Water percolating in the ground and accumulating in groundwater reserves dissolves mineral along the way and is usually classified as *hard* water, depending on the composition of the soil through which it has percolated. Municipal, agricultural, and industrial wastewater streams all have specific contents, for example, high nitrate content in agricultural or high sulfur content in industrial waste.

Water purification is distinct from the more general water treatment entry as the latter covers a more diverse range of waters sources, e.g., agricultural and industrial waste streams or soil decontamination.

Water purification to make water potable is typically performed in treatment plants, but treatment at the point of origin, whether a well or a reservoir, can be the preferred option. Examples include altering the pH of raw water in a well as this could damage piping and pumps from well to plant or controlling aquatic life in a lake after the introduction of foreign species has altered its ecosystem (e.g., zebra mussels in the Great Lakes region in North America), leading to overgrowth of plant life or low oxygen levels. The different nature of water sources requires distinct purification methods to achieve potable water requirements, which are set country by country and are based on the maximum acceptable concentration

of dissolved gases, minerals, solid, and microorganisms that can be found in potable water (Nemerow et al. 2009). Regardless of these differences, the main steps in water purification are similar in water treatment plants around the world. First, sampling is performed at every stage of the treatment process to evaluate quantitatively water quality and to monitor each step's effectiveness. Common quality controls include turbidity, testing for taste and odors, pH, alkalinity, solid residue, or bacteria concentration. For a more extensive treatment of water quality analysis, the reader is referred to the further reading section at the end of this text. Pretreatment processes include screening and sedimentation to remove solids, plants, or other floating debris that could damage the plants' equipment (Pizzi 2010). Smaller particles that will not settle in a reasonable time or can pass screens are traditionally removed using coagulation or flocculation. These particles will resist settling due to their small size (which increase drag resistance) and their surface charge that repels particles one from the other. Coagulation and flocculation act by neutralizing the particles' surface charge, thereby inducing their aggregation in bulkier structures (called flocs) that eventually grow large enough to settle. In modern plants, this stage is more and more replaced by membrane filtration or a combination of coagulation and filtration. The advantage is a significant reduction in process time as well as minor use of chemicals (Koltuniewicz and Drioli 2008). A further sedimentation step, also called clarification, is sometimes added after flocculation to remove large amounts of chemical precipitates resulting from water softening. The latter can also be effectively achieved using nanofiltration membranes (Koltuniewicz and Drioli 2008). Precipitates, flocs from coagulation or flocculation, and microorganisms are removed from water during the filtration process, whereby water passes through filter media (sand, granular activated carbon, garnet, or anthracite) leaving behind the solids. A primary task of the filtration stage is to reduce the water's turbidity, not only for aesthetic reason but also because it interferes with light-activated disinfection (Parker et al. 2009). For further

details on filtration, the reader is referred to the further reading section at the end of this text. Membrane bioreactors, which combine a biological reactor to degrade suspended organic matter with a membrane for solid/liquid separation, are becoming an increasingly popular alternative to the above purification steps due to a reduced footprint and higher-quality output (Judd 2011). The following step in the purification process is water disinfection, where pathogen organisms, such as viruses, bacteria, or fungi, which can cause diseases, are destroyed or removed. Common water-borne diseases caused by incomplete disinfection include hepatitis, caused by a virus; legionellosis, caused by bacteria; or dysentery, caused by protozoa. Disinfection should not be confused with sterilization, which entails the destruction or removal of all microorganisms from water and is required only for specific uses (e.g., high purity water for industrial use). Disinfection can be achieved using heat, UV light, or chemicals. The first, essentially boiling water, is today used only in emergencies or when no other treatment method is available. UV treatment is very effective at removing most pathogens, including the dangerous and hard to remove cryptosporidium. For it to be effective, turbidity has to be low enough not to block the light. Furthermore, natural organic matter and dissolved minerals have also to be removed to prevent fouling of the lamps. UV treatment alone is not sufficient to ensure complete disinfection and is often used in conjunction with chemical treatment, sometimes as a polishing step after the latter.

Chemical treatment is by far the most common disinfection method, with chlorination being the primary process. Chlorine is available in gaseous, liquid, or solid forms and reacts with the different substances present in the water to form either active or inert residuals. Precise guidelines control the choice of chlorine source and its dosing. Other chemical used in disinfection include bromine, which is less stable than chlorine; iodine, which can be easily transported in solid form; ozone, which produces less toxic residuals than chlorine; and potassium permanganate, which is often added to water before chlorine to eliminate humic and fulvic acids, which, upon chlorination,

produce trihalomethane, a toxic substance. Nanofiltration and reverse osmosis membranes have been shown to be effective alternatives, completely removing virus and bacteria (Koltuniewicz and Drioli 2008), though in general are not yet competitive with chemical treatment. For further details on filtration, the reader is referred to the further reading section at the end of this text.

Other water purification processes can include fluoridation, which is applied to achieve an optimal concentration of fluoride ion in water, to provide public health protection from dental caries; remineralization, when reverse osmosis is used during the filtration process as it removes all dissolved ions from the treated water; softening to remove carbonates, sulfates, and nitrates found in groundwater; and anticorrosion and anti-scaling processes which are meant to protect plant equipment and piping from chemical or organic attack.

Emerging Challenges in Water Purification

Micropollutants are compounds found at the ppm- or ppb-level concentration in water and soil that are considered as potentially harmful to the environment and human health. These include different classes of compounds, from pesticides to pharmaceutical active compounds and hormones, surfactants, and person care products (Stuart et al. 2011). For most compounds, there is yet little evidence of the effects of long-term exposure or of slow accumulation in the environment and in human food supply chain (Deblonde et al. 2011). Nonetheless as these results are made available in the scientific literature, it is expected that legislation in developed countries will require their removal from drinking water (Shannon et al. 2008). This will require, most likely, novel detection and removal methodologies for micropollutants, given their very low concentration (Virkutyte et al. 2010).

Nanomaterials, whose characteristic is to have at least one dimension less than 100 nm (10^{-7} m), are a novel class of potentially harmful materials, for which detection and removal strategies from

wastewater are only now being developed (Nowack and Bucheli 2007). At the same time, nanomaterials are also being intensively being investigated to improve removal of contaminants and decrease the energy consumption of wastewater treatment processes (Qu et al. 2012). As the effects of long-term exposure to nanomaterials are not yet known, water regulators and health agencies around the world have adopted a cautious approach, banning or severely limiting the use of nanomaterials in wastewater treatment and water purification (Ganzleben and Hanen 2012).

Water Recovery in Paper Industry by Membrane Operations

Mari Kallioinen

Lappeenranta University of Technology,
Lappeenranta, Finland

Papermaking consumes high volumes of water. In a modern paper mill, the water consumption can be less than 10 m³ water per 1 ton of produced paper, but in older mills the water consumption can be significantly higher. The use of membrane processes enables the reduction of water consumption to values below 10 m³ per 1 ton of produced paper.

In efforts to decrease the water consumption of paper mills, the greatest benefits can be achieved by treating and recycling the effluent streams with greatest volumes. For instance, ultrafiltration of paper machine clear filtrate (a paper machine white water), which can constitute more than half of the total effluent load of a paper mill, enables significant reduction in freshwater use. Ultrafiltration removes from the clear filtrate suspended solids and microorganisms and reduces the amount of organic dissolved compounds (lignin, hemicellulose, etc.). Ions are retained when they are bound, for example, to fibers. The removal of dissolved organic compounds depends on the quality of the clear filtrate and the used membrane, but it is typically between 10 % and 40 %. The clear filtrate purified with ultrafiltration can be used at wire section showers, as sealing water and in dilution of wet-end chemicals. Nanofiltration removes, depending on the clear filtrate, filtration conditions and the used membrane from 70 % to 90 % of dissolved organic compounds (COD, TOC), color, and lignin degradation products. In addition, nanofiltration can retain multivalent ions.

For instance, at SAPPI Ltd Kirkniemi paper mill (Lohja Finland), the use of membrane filtration in recovery of water has made it possible to decrease the freshwater intake to values below 6 m³ per produced ton of paper. At Kirkniemi paper mill, high shear rate cross-rotational

(CR) filters (Valmet Corp.) are used in the ultrafiltration. The membrane area is 1,428 m². When the membrane plant is operated in three stages, 94 % of the clear filtrate (feed) can be recovered into permeate (235 m³/h). In a 7-year period, a very high average flux, 315 L/(m²h) (0.8 bar, 60 °C), has been reported. The produced permeate is used at paper machine showers and for chemical dilutions. A part of the permeate (50 m³/h) from the ultrafiltration is possible to purify further with spiral-wound nanofiltration to replace warm freshwater of the paper machine (Sutela 2008).

The CR filtration technology (Valmet Corp.) has been applied also in the treatment of paper mill waters at the newsprint mill of Holmen Paper in Madrid (Spain) and UPM Kymmene mill in Valkeakoski (Finland). At these mills, approximately 20–50 % reduction in the use of freshwater has been achieved (Sutela 2008). Also vibratory shear-enhanced processing (VSEP) filters, tubular modules, and conventional spiral-wound modules have been used in several mills in purification of paper mill circulation waters (Linpac 2006; Kreutzman and Sutela 2004).

Water is recovered with membranes also from the effluents of the external biological treatment plant of paper mills. For instance, in the Eltmann newsprint mill of Papierfabrik Palm (Germany), nanofiltration has been used since 1999 to purify the effluent and recover water back to the paper-making process. The produced concentrate is first precipitated by lime to remove the compounds, which are difficult to degrade biologically, and then the concentrate is led back to the biological purification process (Schirm et al. 2001). Also membrane bioreactors (MBR) are used in recovery of water at paper mills. One reported example operates in France at the Papeteries du Rhin's paper roll mill, where MBR purifies the mill effluent, and permeate of the process is partly led back to the mill processes (Ramaekers et al. 2001).

Water Recovery in the Paper Industry, Membranes for

Ángeles Blanco and M. Concepción Monte
 Department of Chemical Engineering,
 Universidad Complutense de Madrid, Madrid,
 Spain

There exists a worldwide trend in paper industries to reduce freshwater consumption for environmental and economic reasons (water stress, freshwater savings, and reduction of effluent treatment and disposal costs). In modern paper mills, freshwater consumption can vary between 2 m³ and 20 m³ of water per ton of paper produced, depending on the type of manufactured paper

Water Recovery in the Paper Industry, Membranes for,

Fig. 1 Accumulation of dissolved COD and TOC in recycling paper mill using newsprint and lightweight coated paper as raw material (Miranda et al. 2009)

and on the age of the mill. As the mills increase the closure of their water systems, a considerable accumulation of contaminants exists; this is worse in recycling paper mills. Accumulation of contaminants, as shown in Fig. 1, can affect both product quality and efficiency of the papermaking operations. Therefore, an adequate internal purification of the process waters is necessary to reduce the organic and inorganic load of the water before its recirculation.

Various internal purification techniques are used nowadays to remove the contaminants from the process waters, including membrane-based processes (Nuortila-Jokinen 2003; Monte et al. 2011). For an advanced white water treatment (water removed from the web in the paper machine), complete elimination of suspended solids is necessary, while for the internal treatment of other process waters the elimination of dissolved substances is also required.

Membrane-based processes are able to produce water with different qualities according to the needs of the process. Moreover, the energy consumption of membrane filtration may be economically viable and the modern modules may be fit in existing mills. Furthermore, they may be installed close to the point in which water must be treated. Ultrafiltration is considered as a best available technology in the BREF Integrated Pollution Prevention and Control (2015) to treat the clear filtrate produced in paper mills during the

purification of white water by disk filters. The clear filtrate can constitute more than half of the total effluent load of the mill. Thus, recycling the purified clear filtrate back to the papermaking process significantly reduces the total effluent load. However, clear filtrate must be filtrated by adequate membranes to obtain a high quality permeate which can be reused, for instance as wire section shower water and in the dilution of chemicals, reducing freshwater consumption (Nuortila-Jokinen et al. 2004; Judd and Jefferson 2005; Kallioinen et al. 2010). The improvements of membrane filtration and the development of low fouling membrane processes have made that this technology is now widely used in the paper sector although fouling and erosion of the active layer still remain as critical factors for its further implementation.

The main requirement for a membrane used in the treatment of clear filtrate or process water in papermaking is a high and stable capacity because of the huge volumes of the pulp and paper mill process streams. The main factor causing flux decline and operational breaks in a membrane filtration process is fouling. It originates from the combined effects of different factors on the membrane: process conditions, process water content, and membrane characteristics. The easiest way to optimize the filtration process to ensure a low fouling process is to choose an optimal membrane for filtration, because it is not possible to change

the process conditions or the process water composition (Duranceau 2001).

Membrane fouling can be reduced by using the shear enhanced membrane modules, adjusting the operating parameters, taking into account the interactions between the membranes and the solutes, and applying different pretreatment to the feed stream (Nuortila-Jokinen 2003). Conventional pretreatment strategies, before membrane filtration, include chemical coagulation, adsorption, sedimentation, and flotation. For example, by causing suspended materials to be agglomerated into larger-size units, coagulation can serve as a kind of pretreatment for kidney operations, having the potential to increase throughput and reduce the rate of blockage of pores in an ultrafiltration membrane.

Membrane Material and Cut-Off

Membrane material is being turned out to be more hydrophilic and more or less negatively charged as paper mill wastewaters are mainly contaminated by negatively charged substances, and this creates electrostatic repulsion forces between the membrane and the solutes decreasing permeability and increasing fouling. Regenerated cellulose membrane has been found to be an optimal and stable membrane in operation for purification of paper mill process water, owing to its remarkable hydrophilic properties. Regenerated cellulose is a pure cellulose which has been treated in a chemical bath for better chemical resistance. However, they do not have good performance stability at high temperature. In paper mills, membranes should also be able to perform at temperatures above 60 °C, because the temperature of the process waters increases as the mill water circuits are getting closed. Membranes which have a better thermal and chemical resistance than the regenerated cellulose might be competitive, for instance, polyethersulfone or hydrophilic polysulfone, polypropylene (Cheryan 1998; Duranceau 2001; Puro et al. 2010). Hydrophilic polysulfone has showed better performance to fouling in a recycled paper mill.

On the other hand, under hydrostatic pressure a polymeric porous membrane is compacted leading to a denser membrane structure with smaller pores and lower membrane flux (Kallioinen et al. 2007). In addition to the influence on flux, membrane compaction can affect retention. If the membrane compaction causes a decrease of the membrane pore size or a deformation of the pore geometry, the retention of molecules of the same magnitude as the membrane cut-off value or of smaller molecules than the cut-off value might increase.

Membrane Module Structure

Several modules are used in the paper industries (Table 1). The differences between the traditional modules and the shear enhanced modules are related to the flux and the fouling of the membranes. In the shear enhanced modules, the turbulence created by different systems close to the membrane surface decreases the fouling and, therefore, increases the flux through the membrane. For this reason, the vibration shear enhanced processing and cross rotational filter modules are preferred in internal purification treatments for process water in papermaking, although their application must be evaluated because the vibration and shear may erode the membrane active layer.

Module Operation Parameters

In general, the lower the pressure and the higher the shear on the membrane surface, the higher the flux and the less fouling occurs but membrane erosion may occur.

Papermaking Process Conditions (pH, Chemical Composition, etc.)

The flux is also greatly influenced by the feed pH. Lower fluxes are obtained at acid pH, but it is not always possible to change the conditions of the process. Sudden changes in the pH or

Water Recovery in the Paper Industry, Membranes for, Table 1 Advantages and disadvantages of the membrane module structure

	Modules	Advantages	Disadvantages
Traditional modules	Tubular	Tolerate high concentrations of suspended solids	Low fluxes Poor packing density Very large plants
	Plate and frame	Better packing density	Low fluxes Very easy to plug with suspended solids (fouling)
	Spiral wound	Relatively low price	Low fluxes Very easy to plug with suspended solids (fouling) Pretreatment must be used
	Hollow fiber	Best packing density	Low fluxes Very easy to plug with suspended solids (fouling)
Shear enhanced modules	Vibration shear enhanced processing	High fluxes Reduced fouling	—
	Cross rotational filter		—
	Tubular compact module		—

temperature may set their own demands for the membrane process. Therefore, the membrane should be selected taking into account the extreme conditions that could happen in the process.

Water Recycling in Electroless Plating by Membrane Operations

Hacene Mahmoudi

Science and Technology, Faculty of Technology, University Hassiba Benbouali of Chlef, Chlef, Algeria

Electroplating or metal finishing processes are characterized as water-intensive operations that are associated to a large liquid effluent volume, and by consequence it generates a large volume of

contaminated wastewater. Electroless metal plating is a chemical reduction process that provides a uniform plating thickness on the metal surface plating part. It is a non-galvanic plating method that involves several simultaneous reactions in an ► [aqueous solution](#), which occur without the use of external electrical power. The reaction is accomplished when hydrogen is released by a reducing agent, normally sodium hypophosphite, and oxidized, thus producing a negative charge on the surface of the part. The most common electroless plating method is electroless nickel plating, although silver, gold, and copper layers can also be applied in this manner. The solvent cleaning is the first cleaning step in the plating process using an organic solvent to remove oil-grease from the surface of work pieces. The latter requires high purity rinse water (10–15 M Ω .cm) to avoid any blemishing or deterioration of the plated metal (Wong et al. 2002). Rinsing waters become contaminated during the plating process due to “drag-out” from the previous plating baths. The contaminated rinse waters may contain heavy metals such as chromium, copper, zinc, lead, nickel, and iron, as well as monovalent ions, depending on the plating process and emulsified organic solvent and oil-grease.

Plating wastewater is usually treated with physical and chemical method (conventional techniques), or most commonly followed by biochemical ways such as the activated sludge method, but the treated wastewater is still highly saline and cannot be reused or rejected in the wastewater discharge network. Therefore, in order to produce qualified water that can be recycled in production line, traditional wastewater plant needs more advanced and efficient treatments such as electrolytic reclamation, ion exchange, reverse osmosis, or electrodialysis.

These methods are used not only to solve the problem of heavy metal pollution but should also deal with the loss of the usable metal in the electroplating industry, which is becoming increasingly expensive due to a decrease in the quality of metal ores. In fact, what is needed is an economical method, not only for the removal of

heavy metals from wastewater but also for the recovery of these metals (Benvenuti et al. 2014).

Membrane separation has become increasingly attractive for treatment and recycling of wastewater in mechanical industry as it is highly efficient, easy to operate, and of low cost. However, treatment of wastewater containing organic solvent using a membrane process posed a considerable challenge, as few polymeric membranes can tolerate a wide range of organic solvents. Recently, reuse of spent rinse water from metal plating using reverse osmosis has been studied. High-quality effluent with 45 μ S/cm conductivity was obtained. Integrated membrane process of ultrafiltration/reverse osmosis (UF/RO) for the reclamation of spent rinse water from an electroless plating process can be considered. Ultrafiltration can be both considered for the pretreatment prior to reverse osmosis and for emulsified oil/water separation. Nanofiltration (NF) membranes have properties in between those of ultrafiltration (UF) membranes and reverse osmosis (RO) ones. The significance of this membrane, besides having small pores, is the membrane's surface charges, which allows charged solutes that are smaller than the membrane pores to be rejected along with bigger neutral solutes and salts. Furthermore it is capable of rejecting multivalent ions effectively, and on the other hand lets the monovalent ions pass through. These are the characteristics that make the nanofiltration membrane a potential process to reject heavy metal ions, which in general are multivalent ions. A complex system comprised of microfiltration, UV radiation, carbon adsorption, nanofiltration, and ion exchange was applied for recycling of spent final rinse of an electroless plating operation.

Water Reuse and Recycling in Pulping Plants by Membrane Operations

Mari Kallioinen

Lappeenranta University of Technology,
Lappeenranta, Finland

Pulp production is a water-intensive process. A conventional kraft pulp mill can use up to 40 m³ of fresh water to produce one ton of chemical pulp (Reeve and Silva 2000). The tightening legislation aiming to the protection of environment and the growing lack of pure water resources leading perhaps to limitations in water use at the mills are driving forces to decrease water consumption also at pulp mills. In the future the cost of water might also be higher due to the lack of resources.

There are real-life examples, where membrane technology has already been used in the decrease of freshwater consumption of pulp mills. For instance, at the VHP security paper mill owned by Ugchelen BV (Apeldoorn, Netherlands), a wastewater purification process has been developed, in which dissolved carbon dioxide is used in a flotation process to remove fibers and debris and simultaneously to reduce the effluent pH from 11 to 8.2 prior to a membrane bioreactor (MBR) unit. The MBR operates at thermophilic conditions in order to reduce the need for heating the purified water. A tubular PVDF membrane is installed outside the bioreactor (volume 250 m³). The COD of the influent of the MBR is 3500 mg/L and the COD of the effluent are stabilized to about 500 mg/L. The effluent is recirculated to the mill processes without any detrimental effect in the product quality. The developed wastewater

process has enabled an 80 % reduction in the freshwater intake to the bleaching process of the mill, and the mill wastewater discharge has decreased by 50 % (Joore et al. 2001; Ramaekers et al. 2001; Hepp et al. 2005). In Canada, at the pulp mill in New Brunswick, the evaporator condensate stream was identified to cause significant amounts of BOD and toxicity to the mill effluents, and a reverse osmosis membrane plant was installed to purify this stream and decrease the environmental load of the mill. The permeate of the membrane plant was recirculated to the bleaching process which lead to a 40 % reduction in water consumption (Webb 2002; Anon 2006).

Typically membrane filtration is used at pulp mills in treatment of bleaching effluents prior to the external biological treatment plant, because ultrafiltration improves the biodegradability of the effluent (see entry “► [Paper Pulp Production and Membrane Operations](#)”). The ultrafiltered bleaching effluent could be reused at the pulp mill for instance as washing water but it is often discharged through the biological treatment plant. The challenge in reuse of ultrafiltered bleaching effluents in pulp mill processes is that the permeates contain alkaline earth metals and there is a fear of them to accumulate and cause scaling problems in the circulation systems. Moreover, ultrafiltration does not retain chlorides and their accumulation might increase the corrosion risk in water circulation systems. If the effluents are nanofiltered, the risks caused by non-process elements are decreased, because their retention is higher in nanofiltration than in ultrafiltration. Thus, membrane filtration might enable safe water reuse at pulping processes when a membrane process producing water containing acceptable levels of non-process elements and organic compounds is chosen to be used.

Water Sorption and Diffusion

Harsha Nagar, Sravya Duvvuri, Siddhartha Moulik and S. Sridhar
Membrane Separations Group, Chemical Engineering Division, CSIR-Indian Institute of Chemical Technology, Hyderabad, India

Separation processes occupy a critical place in process industries for isolation of products and recycling of reactants. Membrane technology has found immense prominence in solving challenging separation problems pertaining to wastewater treatment, drinking water purification, solvent

recovery, and gas purification. It has several advantages over conventional methods such as higher selectivity, low energy consumption, and moderate cost-to-performance ratio besides small footprint (Chapman et al. 2008). There are many situations where the target component cannot be separated by distillation, liquid extraction, and evaporation. The different membrane processes wherein water sorption and diffusion occurs are pervaporation, reverse osmosis, forward osmosis, ultrafiltration, nanofiltration, vapor permeation, microfiltration, and dialysis. Each process is dealt with in terms of membrane type, solubility, diffusivity, and effect of operating parameters on the properties.

Forward osmosis (FO): FO is another emerging membrane technology, which has several advantages such as low temperature and pressure requirements. FO process offers nearly complete rejection of a wide range of contaminants and possibly lower membrane fouling propensity compared to traditional hydrostatic pressure-driven membrane processes. As a result, FO process has been used extensively in wastewater treatment; seawater desalination; processing pharmaceutical, food, and dairy products; power generation; and protein enrichment. In FO, the feed and draw solutions are brought into contact through a semipermeable membrane as shown in Fig. 1. Due to difference in osmotic pressure ($\Delta\pi$) across the membrane, the solvent, usually water, flows from a region of higher concentration to lower solvent content. The osmotic pressure of a solution is commonly defined as

$$\pi = \frac{n}{V_m} iRT \quad (1)$$

where n is the number of solute molecules, V_m is the volume of pure solvent, i is the dimensionless van't Hoff factor, R is the ideal gas constant, and T is the temperature. In general, water flux (J_w) in FO process is given by the following relationship:

$$J_w = A\sigma\Delta\pi \quad (2)$$

where A is the water permeability of the membrane and σ is the reflection coefficient.

Water flux through the membrane mainly depends on choice of membrane material which allows passage of only water with retention of solute molecules type of draw solution used. Generally, membranes composed of a dense hydrophilic active layer casted onto a highly porous mesh-like substrate are usually employed. Figure 2 describes the mass transport of solvent molecules through thin-film composite (TFC) FO membrane from feed side to draw solution. External concentration polarization (ECP) occurs near the active membrane layer on the feed side, thus increasing the feed concentration from $C_{f,b}$ to $C_{f,m}$. As water permeates through the membrane, the draw solution gets more diluted and consequently concentration of the solute particles gradually

decreases at the membrane interface ($C_{d,m}$) when compared to bulk concentration ($C_{d,b}$) thereby leading to dilutive internal concentration polarization (ICP) within the porous support layer. The presence of both ECP and ICP results in lower osmotic pressure gradient across the active layer as against to bulk osmotic pressure difference.

Reverse osmosis (RO): The principle of RO process shown in Fig. 1 illustrates the phenomenon of osmosis, osmotic pressure, and reverse osmosis. Osmosis is now also called FO to differentiate it from RO which is a more widely used process. RO is the application of an external pressure greater than the natural osmotic pressure of a feed solution to force water to flow from the feed solution side to the pure-water side through semi-permeable membrane. As a thumb rule, it can be stated that 1000 ppm of NaCl solution exerts an osmotic pressure of 0.7 atm which means that RO can occur only if the applied pressure is greater than 0.7 atm. Thus for seawater which contains 3.5 % w/v salts, the applied pressure must be greater than 25 atm. RO is a combination of membrane interfacial phenomenon and fluid transport under pressure through capillary pores. For providing freshwater, RO membrane separation technique plays an important role. In this process, raw water is passed through a semipermeable membrane using pressure as a driving force for removing impurities, organic contaminants, and salts for producing purified water. Basically two types of

Water Sorption and Diffusion, Fig. 1 Principle of RO and FO process

Water Sorption and Diffusion,

Fig. 2 Principle of water sorption and diffusion in FO process

Water Sorption and Diffusion,

Fig. 3 Principle of water sorption and diffusion in PV

membranes have been used for RO, TFC and cellulose acetate membranes. During the preparation of TFC membranes by interfacial polymerization, a microporous polysulfone support membrane is further reinforced by a porous non-woven polyester backing layer. An ultrathin active layer of polymer film produced by interfacial polymerization is used to permeate water with rejection of salt. An important characteristic of TFC membrane is the sorption of water by the active layer. This is important because higher water sorption results in the membrane having greater water permeability. The selectivity of RO membranes has been correlated with the free volume of the active layer. Water sorption mechanism depends on both physical structure and chemical composition of the polymeric membrane. According to research, the transport of water molecules through a polymer at a temperature below its glass transition temperature is a three-stage process in which initially the water molecules get sorbed on to the membrane surface at the feed side, then diffuse through the thickness, and finally get desorbed on the permeate side. During diffusion some of the water molecules are bound to dense polymeric matrix leading to the swelling of membranes. In some cases, the kinetics of water diffusion mechanism can also be described successfully by Fick's law of diffusion. The water sorption occurs in the polymeric membrane due to the electrostatic attraction

between water and the functional groups of the polymers. The permeation rate is a function of solubility or the membrane separation factor which is a measure of the quality of separation that the membrane provides and diffusivity or the mass flux across the membrane. Solubility is a thermodynamic property whereas diffusivity is a kinetic parameter, both affecting perm selectivity (Mulder et al. 1985).

Pervaporation (PV) and vapor permeation (VP): PV membrane technique has exhibited tremendous potential for solvent dehydration, separation of azeotropes, close-boiling compounds, and organic–organic liquid mixtures. It can also be applied for recovery of small quantities of value-added compounds such as flavors and fragrances and removal of hazardous impurities, viz., volatile organic compounds (VOCs) such as vinyl chloride, benzene, and toluene from industrial effluents and for the enhancement of reaction yields in esterification and fermentation processes through continuous removal of water or the organic products. Figure 3 represents the principle of water sorption and diffusion in PV.

In PV, the liquid feed is maintained at a temperature close to its saturation point and then exposed to the membrane which allows one component, say water, to preferentially pass through the barrier. The downstream side of the membrane is kept under vacuum wherein permeating water is collected as vapor and then condensed. The

Water Sorption and Diffusion,**Fig. 4** Schematic diagram of dialysis process**Water Sorption and Diffusion,****Fig. 5** Principle of UF

composition of this vapor is largely different from that produced by a conventional distillation process. The principle of VP is analogous to PV with physical state of feed being the only difference in the process. In VP, the feed is a mixture of vapors in saturated condition, and in PV, the feed is in liquid state. The driving force in PV is maintained through vacuum or an inert sweep gas in the permeate side. With absence of any phase change in VP, the additional cost of heat equivalent to the enthalpy of vaporization is not required. The other advantages of VP include the elimination of concentration polarization at the membrane surface.

Dialysis: This process involves the transportation of solutes and water due to concentration gradient across a porous membrane. The main application includes purification of blood by the removal of excess salts and water when the kidneys are malfunctioning. The other applications of dialysis are recovery of NaOH from cellulose-steeping liquors (Cooney et al. 1974) and removal of alcohol from beer. Figure 4 represents schematic diagram of dialysis process.

Ultrafiltration (UF): UF is used for the separation of macromolecules with lower operating pressure. UF membranes fractionate the components of a liquid predominantly in a pore size range of 2–200 nm. UF membranes are used to remove viruses, color, odor, and some colloidal natural organic matter. In this process, the feed is pressurized through the membrane to remove colloidal organic matter, viruses, color, and odor with a pressure ranging from 2 to 10 bar. The membrane acts as a filtering medium, allowing only dissolved substances of smaller molecular size than the membrane apertures to pass through them along with water. The other materials that cannot pass through the membrane are usually bigger compounds like enzymes, proteins, and antibiotics which get enriched in the retentate. The principle of the process is shown in Fig. 5.

Microfiltration (MF): The separation of very fine colloidal solids from a solution in the range of micro and sub-micrometer is named as microfiltration. Water present in the feed passes through the membrane, whereas fine suspended

Water Sorption and Diffusion, Fig. 6 (a) Ceramic MF membrane. (b) Laboratory MF/UF system

particles and colloidal impurities are retained. The pressure ranges from 0 to 2 bar and the pore size of the membrane ranges from 0.1 to 5 μm . The most important applications of MF include separation of water/oil emulsions, concentration of colloidal substances, and pretreatment in RO, NF, and UF systems. MF is also typically used for turbidity reduction and removal of giardia and cryptosporidium.

Different types of membranes are used for microfiltration such as polymeric and inorganic membranes which are present in different modular configurations such as spiral, tubular, hollow fiber, ceramic, and stainless steel. Figure 5 exhibits a ceramic MF module. An integrated MF/UF laboratory system is shown in Fig. 6 which is used for the pretreatment of domestic and industrial wastewater.

Nanofiltration (NF): This process allows monovalent salts to pass through the membrane

while retaining larger species such as multivalent salts. The pore size in a NF membrane corresponds to 0.5–2 nm. This process is extensively used in food and beverage industries for water purification. But its major application could be in the pharmaceutical industry since most commercial drugs have molecular weight cutoff in NF range. Additionally, NF application can be extended to solvent recovery provided solvent-resistant membranes are developed. The basic principle in which NF works is similar to UF, MF, and RO, but the distinguishing feature between them is their effective pore size and charge-based exclusion known as Donnan's principle. Reverse osmosis membranes reject all but the very smallest species, while MF allows considerably larger particles to pass through it as shown in Fig. 7.

To understand the mechanism of water sorption and diffusion in polymers, it is important to

Water Sorption and Diffusion,

Fig. 7 Principle of NF

analyze the transport phenomena happening within the membrane matrix (Maggana et al. 1999). In a membrane process, the polymer is usually kept in a moist environment, where water molecules along with low-molecular-weight substances can easily penetrate through to the other side even at room temperature, which brings about certain structural and physical changes.

But in perspective of enhancing the membrane performance, there is often a trade-off between selectivity and flux. Increasing one leads to a decrease in the other during performance modification. Regarding the performance, an index called the pervaporation separation index (PSI) is used which is expressed as selectivity $\times$ flux. Although this is an index useful in comparing different membranes, there could be instances wherein membranes, one having a low selectivity and high flux and the other with a high selectivity but low flux, can end up with the same PSI. Therefore, higher PSI is not an indication of superiority of a membrane. Separation performance also depends on appropriate membrane selection. Mainly, two classes of membranes are being used in most pervaporation operations: polymeric membranes and inorganic barriers. In polymeric membranes, organic polymer chains are cross-linked together, forming tiny voids between the segments through which molecules can diffuse. However, inorganic membranes have

increasingly become a focus of research due to several advantages over polymeric membranes such as solvent resistance and the ability to operate at higher temperatures since these are fabricated from ceramics or zeolites. By combining the advantages of both these two types of materials, a third class of membranes defined as composites are manufactured which consist of an organic polymeric membrane containing inorganic particles dispersed throughout. These are also commonly termed as mixed matrix membranes.

Membranes having a hydrophilic nature are generally used in dewatering of organic solvents through pervaporation (Lu et al. 2003). The component which comes out from the dense membranes follows a solution–diffusion process, and therefore, sorption of component in the membrane plays a major part in separation performance. The interaction between water and membrane is of high significance in hydrophilic membranes. Therefore, substantial research is going on to understand the mechanism of water sorption in hydrophilic polymers. Based on different studies, it is observed that when the polymer is in condensed state after the sorption of water, the mechanical and physical properties of the membrane change which enhances the mobility of the polymer chains and decreases the glass transition temperature, wherein water molecules play the role of a plasticizer. The hydrophilicity of a membrane is the measurement of the contact angle

between air and a drop of water on the membrane surface. This elucidates the degree of the material with respect to water. This measurement can also be made with respect to any solvent to be dehydrated to assist the membrane selection. Depending upon the contact angle between the solvent and the membrane, the nature of wettability allows water to preferentially get sorbed onto the membrane surface, forming an aqueous layer of resistance to mass transfer. This layer allows water to permeate through the pores but resists other components. By utilizing this behavior, various solvents can be dehydrated. According to Chapman et al. (2008), if the membrane is wetted by the solvent (water), then the solvent will enter and pass through the membrane, whereas for non-wetting solvents, additional pressure is required to be applied. For this, bubble-point procedure can be used to determine pore diameter and pore size distribution. In this test, the minimum pressure or bubble point at which the liquid is forced out of the membrane by an inert gas is determined. When the molecular sizes needed to be separated are relatively small such as low-molecular-weight solvents and water, then conventional processes like distillation are not effective due to azeotrope formation, close-boiling points, and high energy demands. A wide variety of membranes can be used for different types of applications. For the dehydration of solvents that contain smaller amounts of water, as compared to any other components, hydrophilic membranes are preferable to enable retention of the organic molecules. On the other hand, for separating small amounts of solvent from water, a hydrophobic membrane is more suitable (Madhumala et al. 2014). This choice ensures low running cost since PV is the only membrane process apart from MD which involves phase change and therefore high enthalpy of vaporization of either water (540 Kcal/kg) or the organic liquid. Dipole–dipole interactions, hydrogen bonding, and ion–dipole interactions between water and the membrane material are the basic forces involved in the hydrophilic PV.

To measure the sorption value of the hydrophilic membrane, small pieces of known weights are immersed in known concentrations of feed

solutions for time periods of 48 h each to enable membranes to reach equilibrium. After removing excess water, the membrane is weighed to determine the amount of water sorbed. The swelling degree is then calculated as follows:

$$DS = \frac{M_s - M_d}{M_d} * 100 \quad (3)$$

where M_s and M_d are the mass of the swollen and dry membranes, respectively. Organic concentration in membrane (Sunitha et al. 2013) is given by

$$\text{Organic concentration} = \frac{M_d - M_o}{M_s - M_o} * 100 \quad (4)$$

To further investigate the transport phenomena through the membranes, basic diffusion studies can be performed. According to Fick's law of diffusion, the ratio of the amount of liquid sorbed at a certain time t (M_t) to the amount sorbed at equilibrium (M_∞) depends on the square root of time:

$$\frac{M_t}{M_\infty} = \frac{4}{l} * \sqrt{\frac{D * t}{\pi}} \quad (5)$$

where M_t and M_∞ are the amount of solvent sorbed at time t and equilibrium, respectively. D is the diffusion coefficient and l is the membrane thickness. Sorption coefficient is determined by

$$S = \frac{M_\infty}{M_p} \quad (6)$$

The permeability coefficient (P) is the combined effect of both solubility (S) and diffusivity (D) which is calculated as:

$$P = D * S \quad (7)$$

Sunitha et al. (2013) reported a variation of swelling ratio with immersion time indigenously synthesizing membranes in eight different liquid mixtures. Table 1 shows some experimental results pertaining to degree of swelling and diffusion coefficient.

Water Splitting

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

Water splitting means a chemical transformation that separates water into its elements which are molecular oxygen (O₂) and molecular hydrogen (H₂). The transformation can be done by various processes such as electrolysis, photochemical, photocatalytic, thermal decomposition.

Electrolysis is a method of separating elements chemically bounded into compounds by passage of an electric current through them: in the case of electrolysis of water, the latter is decomposed (splitted) into gases O₂ and H₂. When energy is obtained from light, photochemical and photocatalytic devices can be used, and the system that splits water into hydrogen and oxygen is also named artificial photosynthesis (Devens et al. 2009).

Water splitting over a semiconductor photocatalyst using solar energy is a promising process for the large-scale production of clean, recyclable H₂ at temperatures close to the ambient one. Numerous attempts have been made to develop photocatalysts that function under visible light irradiation to efficiently utilize solar energy (Kazuhiko 2011; Valdes et al. 2012). The photocatalytic splitting of water under visible light irradiation is a greatly desired reaction system for hydrogen production. However, powdered photocatalysts always produce a gas mixture of hydrogen and oxygen in such a reaction, and thus, a separation process for the gas mixture is required before the hydrogen can be effectively utilized. Construction of a photocatalytic system enabling the separate

evolution of hydrogen and oxygen from water (e.g., by means of a membrane) under visible light irradiation and absence of sacrificial agents using a Z-scheme (Abe 2010) is, therefore, of vital interest. In this Z-scheme methodology, hydrogen and oxygen are generated photocatalytically in different cells that are illuminated and separated by a membrane. An electrolyte is used to ensure the electroneutrality in each cell and to allow charge transfer from one compartment to the other. One suitable electrolyte is the $\text{Fe}^{2+}/\text{Fe}^{3+}$ redox pair. A Nafion membrane is a suitable barrier between the two compartments of the reactor because of its chemical and physical properties (Seger et al. 2007). The uptake characteristic of different cations (Fe^{3+} , Cu^{2+} , and Ni^{2+}) by Nafion 117 which is commonly used as separator for different chemical processes was also investigated (Ramírez et al. 2010).

Thermal decomposition (or thermolysis) is another approach for water splitting: it is a chemical transformation that breaks a substance into at least two chemical substances when heated. At elevated temperatures (e.g., 2200 °C), water molecules can decompose, but using catalysts, lower temperatures can be used to obtain hydrogen and oxygen.

Solar energy can be used for thermal decomposition of water via an integrated thermochemical reactor/receiver system (Agrafiotis et al. 2005). A multichannel honeycomb ceramic supports coated with active redox reagent powders, in a configuration similar to that encountered in an automobile catalytic converter, have been used. Iron-oxide-based redox materials, capable to operate under a complete redox cycle, could take oxygen from water producing pure hydrogen at reasonably low temperatures (800 °C) and could be regenerated at temperatures below 1300 °C. Ceramic honeycombs capable of achieving temperatures in that range when heated by concentrated solar radiation were assembled in a dedicated solar receiver/reactor. The operating conditions of the solar reactor were optimized to achieve adjustable, uniform temperatures up to 1300 °C throughout the honeycomb, making thus feasible the operation of the complete cycle by a single solar energy converter (Agrafiotis et al. 2005).

⁵Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

The water transport through ion-exchange membranes is caused by osmosis and by

Water Transport in Ion-Exchange Membranes, Fig. 1 Schematic drawing illustrating the test cell for determining the osmotic water flux through an ion-exchange membrane

electroosmosis. The osmotic water transport is the result of concentration differences between the two solutions separated by the membrane. Electroosmosis refers to the water transported in the hydration shell of the ions migrating through the membrane due to an electrical potential gradient. The osmotic water transport is measured using a two-compartment cell containing pure water in one compartment separated by the membrane from the second compartment containing a salt solution. The volume change in the compartments is determined as a function of time in two horizontal capillaries connected with the compartments as indicated in the schematic drawing of Figs. 1 and 2, which illustrate the experimental setup to determine the water transport in osmosis and electroosmosis.

In osmotic water transport measurements, one cell is filled with water and the other with a salt solution. The water flux from the cell filled with water into that filled with the solution is measured in the horizontally arranged capillaries as indicated in Fig. 1. Since the osmotic pressure is a linear function of the concentration of a solution, the osmotic water transport increases linearly with the salt concentration.

The electroosmotic water transport is expressed by a transport number in analogy to the transport number of ions and is given by:

$$T_w^m = \frac{FJ_w}{i} \quad (1)$$

Here is the transport number of water through a membrane, F is the Faraday constant, i is the current density, and J_w is the water flux expressed in moles per unit area and time. In the electroosmotic water transport measurement, a direct current is applied using reversible electrodes, i.e., Ag/AgCl electrodes. Both compartments of the test cell are filled with a test solution of identical concentrations. The electroosmotic water transport of a cation-exchange membrane is a function of the migration of the cation and is determined by water connected to the ion in its hydration shell. The electroosmotic water transport through a cation-exchange membrane due to the migration of a Na^+ -ion can be determined by measuring the volume change in the two compartments of a test cell filled with a NaCl solution as indicated schematically in Fig. 2.

In the test it is assumed that the membrane is strictly semipermeable, i.e., it is only permeable for Na^+ -ions. However, the volume in the two compartments of the cell is not only the result of the water transport. The volumes of the cells are also changed by the electrode reactions. At the anode Cl^- -ions disappear and at the cathode Cl^- -ions are generated according to the following reaction scheme:

and

The electroosmotic water transport is calculated from the volume change in the two compartments:

$$\begin{aligned} \Delta V_F &= \Delta V_{\text{tot}} + \Delta \bar{V}_{\text{AgCl}} - \Delta \bar{V}_{\text{Cl}^-} \\ &= T_{\text{Na}^+}^m n_w^{\text{Na}^+} + \bar{V}_{\text{Na}^+} \end{aligned} \quad (2)$$

Here ΔV_{tot} and ΔV_F are the total volume change and the volume change, respectively, due to electroosmosis in the cell when electrical charges of

Water Transport in Ion-Exchange Membranes,

Fig. 2 Schematic drawing illustrating the test cell to determine the electroosmotic water transport

1 Faraday are transported, is the partial molar volume of AgCl and Ag, is the transport number of Na^+ -ions in the membrane, and is the number of water molecules carried by on Na^+ -ion.

The electroosmotic water flux is:

$$\Delta V_F = T_w^m \bar{V}_w \quad (3)$$

Here is the water transport number, ΔV_F is the electroosmotic water flux, and is the partial molar volume of water.

Different cations show rather different electroosmotic water transport numbers. Ions with a relatively large hydration shell such as the Na^+ -ion have a water transport number of 6–8. Protons have a very low water transport number of less than 3 because of the different transport mechanism which has been discussed earlier. The water transport number is decreasing with increasing salt concentration.

Characterization of Special Property Membranes

In many applications of electrodialysis and related processes, special property membranes are

required. For instance, for the pre-concentration of seawater for the production of table salt, membranes with a low permeability for divalent ions are required. In diffusion dialysis anion-exchange membranes with high proton permeability or cation-exchange membranes with high hydroxide ion permeability are needed, and in bipolar membrane applications generally acid and base blocking monopolar membranes as well as efficient bipolar membranes with a low electric resistance and good water dissociation capability are needed (Pourcelly et al. 1990). Most monopolar membranes can be characterized by applying the procedures described earlier. In addition to the electrical resistance and the permselectivity, the water dissociation capability is for bipolar membranes of prime importance. Therefore, membranes are generally characterized by a so-called current versus voltage plot. Determination of the current through a bipolar membrane as a function of the applied voltage provides information about the water dissociation, the electrical resistance, and the salt leakage of the membrane. A typical current versus voltage curve of a commercial bipolar membrane is shown in Fig. 3 (Krol et al. 1998).

Water Transport in Ion-Exchange Membranes,

Fig. 3 Current density versus applied voltage curve schematic drawing indicating three distinct areas where the current is determined by the salt transport, the water dissociation, and by the water diffusion into the reaction zone of the membrane

As illustrated in the schematic drawing, three distinct areas in the current versus voltage curve can be identified. The first area is characterized by a linear increase in current with the applied voltage until a limiting value of ca. 1 mA cm^{-2} is reached at ca. 0.1 V. A further increase in the applied voltage does not lead to an increase in the current. The current in this region is the result of salt transport from the transition region of the bipolar membrane into the outside solutions due to the driving force of the applied potential. Up to an applied voltage of ca. 0.1 V, this transport is compensated by salt diffusion from the outside solutions into the bipolar membrane due to a concentration gradient. The salt transport out of the membrane cannot exceed the diffusive salt transport into the membrane independent of the applied voltage. Thus, a steady state is reached and the current is limited by the salt diffusion into the membrane until the voltage drop across the membrane reaches 0.6–0.8 V. The drastic current increasing when the applied voltage is increased further is the result of the transport of H^+ and OH^- ions that are produced within the bipolar membrane. In the region between 0.5 and 1.2 V applied voltage and a current density of up to 500 mA cm^{-2} , the current is carried by H^+ and OH^- ions which are provided by the water dissociated. If the applied voltage has reached ca. 1.2 V, a further increase does not lead to a significant increase in current. This limitation of the current density is the result of a decrease in the H^+ and OH^- ion

concentration in the transition region of the bipolar membrane which is limited by the water diffusion rate from the outside phases into the membrane. Operation of the membrane in the third, i.e., the water diffusion limited region, generally leads to a destruction of the membrane (Krol et al. 1998).

In addition to determining the current density as a function of the applied voltage more complex testing methods such as impedance spectroscopy (Zabolotsky et al. 1978; Holdik et al. 1998) or chronopotentiometric measurements (Wilhelm 2001) are used to obtain more detailed information about the mechanism of the water dissociation and the resistance of the bipolar membrane.

Water Treatment by Electrodialysis

Hacene Mahmoudi

Science and Technology, Faculty of Technology, University Hassiba Benbouali of Chlef, Chlef, Algeria

Clean water, free of toxic chemicals and pathogens, is essential to human health (Montaña et al. 2013). Treatment processes for the production of freshwater from any kind of water sources such as groundwater and surface water, as well as recycled process and wastewater, are becoming more and more important to cope with rapidly increasing water demand. Increased nitrate concentrations, mainly caused by non-clarified wastewater or excessive application of artificial fertilizer and manure in agriculture, are found quite often in groundwater. Also many surface waterworks are confronted with the necessity to remove dissolved ionic substances. Common treatment methods used at waterworks are a combination of chemical oxidation, coagulation-flocculation, sand filtration, and disinfection. However, in recent years, membrane technology has become an extraordinarily useful tool for the production of freshwater. Recent advances suggest that many issues involving water quality could be resolved or greatly ameliorated by using ultrafiltration (UF), nanofiltration (NF), reverse osmosis (RO), electrodialysis (ED), or electrodialysis reversal (EDR) processes (Montaña et al. 2013).

UF and NF membrane filtration processes work by excluding contaminants using pore-size constraints when water under pressure is forced to pass through a semipermeable membrane with different pore sizes. The RO membrane works as a molecular filter that rejects positively and negatively charged ions based on molecular weight when pressurized water is forced through the

membrane (Montaña et al. 2013). In contrast, the driving force for separation in ED and EDR processes is an electric potential, and an applied current is used to transport ionic species across selectively permeable membranes. The principal difference between ED and EDR is that EDR includes the additional step of a change in electrode polarity every 15–20 min, thus causing a reversal in ion movement. This step minimizes scale buildup on the membranes which means that EDR can operate for longer time periods between cleanings (Montaña et al. 2013).

Treatment processes are required, which are reliable, selective, easy to operate, and have low costs. Electrodialysis fulfills these requirements quite well. The special features of electrodialysis are high water recovery, selectivity, low chemical demand, and low energy demand (Hell and Lahnsteiner 2002).

Water Treatment by Membrane Operations

Davide Mattia

Department of Chemical Engineering, University of Bath, Bath, UK

Water treatment by membrane operations covers a wide field of technologies and processes related to the treatment of municipal, agricultural and industrial wastewater, water purification, desalination, water recovery from wetlands, and remediation of contaminated soil.

In all cases the motivation to treat wastewater is given by the concurrent scarcity of freshwater and the increasing demand for it by a growing world population. Furthermore, the increase in human population has cascading effects on water availability and treatment with agriculture and industrial use polluting groundwater and high population concentration in cities producing ever-larger volumes of waste to treat. In all these instances, membranes play a key role in controlling the composition of the treated water stream, via the removal of toxic substances and the recovery of water for reuse. This can be attributed to the ability of membranes, with the appropriate pore or MWCO size, to provide an effective barrier to any contaminants present in the water to treat. As the size of these contaminants, from ions to bacteria, varies several orders of magnitude, water treatment plants often contain several membrane processes in series with decreasing MWCO.

Microfiltration (MF) and ultrafiltration (UF) membranes are mainly employed to remove solid particles and microbes/bacteria (Cheryan 1998). These are often used as a pretreatment step for nanofiltration (NF) and reverse osmosis (RO) membrane processes that can remove natural organic matter, viruses, and ions (Van Der Bruggen et al. 2003). Each stage is complemented by a host of other treatment processes (e.g., mesh screening, coagulation, UV disinfection, ozonation, etc.). An example of an integrated membrane process is represented by membrane bioreactors (MBRs), where a biotreatment process to degrade suspended organic matter is coupled with a membrane to retain the biomass, producing a clarified and disinfected effluent (Judd 2011). MBRs are rapidly supplanting legacy activated sludge treatment plants for municipal wastewater due to a smaller footprint, reduced use of chemicals, and superior quality of the treated water (Leiknes 2009). Current MBR plants employ UF membranes with NF ones being currently assessed as they can also remove viruses and some organic molecules,

reducing the need for further treatment downstream. Membrane fouling remains the main obstacle toward more widespread adoption of MBRs as it requires expensive gassing and chemical cleansing to avoid dramatic flux reductions caused by the formation of biofilms on the membrane feed side. Another example, in earlier stages of development compared to MBRs, is the coupling of a membrane with oxidation of pollutants via photocatalysis (Romanos et al. 2013). This approach has significant potential as the organic pollutants can be fully mineralized into water and carbon dioxide, producing no sludge nor requiring chemical cleansing. The long-term activity and stability of the photocatalyst remains the challenging aspect of this promising technology.

Nanofiltration membranes in water treatment are mainly used for softening water, the reduction in the concentration of calcium and magnesium ions, particularly groundwater. Typically, thin film composite membranes are used, though the high pressures required somewhat limit their use. NF membranes are also effective at removing natural organic matter, viruses, and pesticides, the latter of particular importance for treatment of agricultural waste (Van der Bruggen and Vandecasteele 2003).

Reverse osmosis membranes often represent the so-called polishing step in water treatment, thanks to the ability to remove dissolved ions as well as arsenic and small organic molecules (Van Der Bruggen et al. 2003). RO membranes are also very effective at removing nitrates originating from the intense use of fertilizers in agriculture. Rejection of boron by RO membranes remains low under typical operating conditions. RO membranes are also the technology of choice for obtaining freshwater from sea- and brackish water, at the cost of significant energy expenditure to force the saltwater through the membrane. Furthermore, RO membranes require extensive pretreatment steps to remove solids, particulate, and organic matter (Voutchkov 2013). Some RO membranes also require dechlorination of the feed

to prevent swelling of the membrane selective layer with consequent loss of ion rejection.

Nitrates, present in agricultural waste as a consequence of the use of pesticides and in some manufacturing waste streams, are highly toxic and difficult to remove as they are water soluble and do not bind to soil. Membrane denitrification has been extensively investigated. RO membranes are capable of removing nitrates below legal limits but high running costs and require the remineralization of the treated effluent before it can be released. Since nitrates are monovalent ions, NF membrane can only remove a fraction of them and has been used as a first step before RO, obtaining lower overall costs (Van der Bruggen and Vandecasteele 2003). MBRs, using UF membranes, have also proven to be effective and economical at denitrification (McAdam and Judd 2006).

Sulfates are present in water streams originating from a variety of sources, including waste streams from pigment and clothing industries, mining, as well as municipal gray waters as part of shampoos and detergents. They also can originate from coal combustion, leading to acid rain, though this source has been significantly reduced in the last 30 years.

Nanofiltration is the method of choice to remove sulfates and is extensively used in industry (Košutić et al. 2004), for example, in treating waste from chlorine production plants containing sodium sulfate or treating waste produced by consumer product manufacturers (Gawaad et al. 2011). Waste containing high percentages of sulfates from gold and coal mining in South Africa has also been successfully treated using NF membranes.

Phosphorous compounds are present in high concentrations in the waste streams of several industries, including detergent manufacturing and metal coating processes. Left untreated, the high phosphorous leads to an overgrowth of algae in the sea, leading to the formation of dead zones where no fish are present due to a lack of available oxygen in the seawater. A well-known example of this phenomenon is in the Gulf of Mexico at the estuary of the Mississippi River. RO membranes

are effective at removing phosphorous compounds as well as nitrates and ensuring high-quality water at a high cost. A more effective solution is the use of crossflow microfiltration processes, sometimes used in conjunction with iron-based precipitants (Dittrich et al. 1996).

Fluoride is naturally present in groundwater and a certain content (~0.5 ppm) is necessary to protect the teeth, whereas higher concentrations have adverse health effects. Nanofiltration is the method of choice to regulate fluoride concentration in drinking water (Choi et al. 2001), as it does not require the remineralization step necessary when using RO. Electrodialysis has also been successfully employed to produce drinking water with low fluoride concentration (Amor et al. 1998), though NF has been found to be more effective.

atomically smooth and chemically homogeneous. Conversely, very few solids are atomically flat. Wetting on rough surfaces was first considered by Wenzel (1936). In the Wenzel state, where the roughness grooves are completely filled with liquid, the contact angle (θ_w) can be described by

$$\cos \theta_w = R_f \left[\frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}} \right] \quad (1)$$

where R_f is the surface roughness factor, which is defined as

$$R_f = \frac{\text{Actual area}}{\text{Projected area}} \quad (2)$$

Combining Wenzel equation with Young's equation yields

$$\cos \theta_w = R_f \cos \theta_C \quad (3)$$

Since the roughness factor is always larger than unity in practical situations, it is obvious that the apparent angle on a roughened surface will become smaller if its intrinsic contact angle on a smooth surface is less than 90° . Similarly, the apparent contact angle will be larger, if its intrinsic contact angle is larger than 90° (Fig. 1).

Wenzel Model, Fig. 1 Liquid droplet on a rough surface. The contact angle can be predicted by Wenzel model (Hsu 2010)

Wet Chemistry Method for Ceramic Membrane Preparation

Zhaoliang Cui

State Key Laboratory of Materials-Oriented Chemical Engineering, College of Chemistry and Chemical Engineering, Nanjing Tech University, Nanjing, China

The **wet chemistry method for ceramic membrane preparation** is a method to fabricate ceramic ultrafiltration membranes directly derived from the nanoparticle suspension that was the intermediate product prior to drying and calcination in the synthesis of nanoparticles (Fig. 1). Traditionally, ceramic ultrafiltration membranes

are usually produced by the sol-gel method, for which sensitive control is required and the reagents used impact environment. Wet chemical method was developed as an alternative for ceramic ultrafiltration membrane preparations (Ding et al. 2006). This technique was developed based on the state-particle-sintering process, which is an alternative for ceramic ultrafiltration membrane preparation (Cortalezzi et al. 2003). The state-particle-sintering method faces a problem that nanoparticles are easy to grow and form aggregates during the drying and/or calcination and it is very difficult to disperse these aggregated nanoparticles. The wet chemical method directly derives ceramic filtration membranes from the nanoparticle suspension that was the in-process product prior to drying and/or calcination in the synthesis of nanoparticle. This procedure begins with suspension which is the in-process product prior to drying and/or calcination in the nanoparticle synthesis. Thus, the nanoparticles exist entirely in an aqueous environment prior to forming a coating layer by dip coating and do not have an intractable problem of dispersion (Ding et al. 2006).

Whey Demineralization with Membrane Operations

Mikel Duke¹ and Todor Vasiljevic²

¹Institute for Sustainability and Innovation, College of Engineering and Science, Victoria University, Melbourne, VIC, Australia

²Advanced Food Systems Research Unit, College of Health and Biomedicine, Victoria University, Melbourne, VIC, Australia

There are various reasons for demineralization in whey processing. Minerals in whey cause issues including (Daufin et al. 2001):

- Slow lactose crystallization
- Fouling in MF and UF used for producing protein concentrates and isolates
- Nutritional imbalance in human and infant foods

Demineralization is therefore advantageous in whey processing for various performance and product reasons. Generally, minerals affect the flavor, functionality, and value of whey products justifying the use of demineralization systems. Electrodialysis (ED), ion exchange (IE), and nanofiltration (NF) are well-known operations achieving demineralization of 25–95 % (Daufin et al. 2001; Greiter et al. 2002). ED and IE are considered costly to operate in terms of equipment and running costs and produce large volumes of waste effluent that must be treated (Daufin et al. 2001). NF has advantages over ED; for example, it is more selective to separate

monovalent ions over divalent ions. Also, this selectivity is not as significantly altered as in ED, which is impacted by protein adsorption on the membranes due to the applied electrical field. The fouling can be managed by separation of concentrate loops to two different loops, and pulsed electrical fields can minimize fouling; however, the compromise is increased processing times (Casademont et al. 2009). Losses of lactose and proteins are lower in NF than in ED and IE, respectively. NF is therefore showing promise as a process to be more cost-effective, particularly in terms of reduced energy consumption, but can only achieve partial demineralization (Brans et al. 2004; van der Horst et al. 1995).

Major applications of demineralization address the three issues listed above, and is being utilized during processing of whey streams as part of lactose crystallization. In this application, lactose is depleted of minerals by NF prior to sending to the crystallizers. The demineralization step leads to higher lactose yields (Daufin et al. 2001), where solid lactose is produced. Refined lactose is valuable in the production of baby foods, sweets, baked goods, sauces, and dressing (Henning et al. 2006). In concentration of whey, ED is used for demineralizing UF concentrate to produce whey protein concentrate (WPC). The WPC (35–80 % protein) after demineralization is mixed with lactose and nonfat milk solids in the production of infant formula (Bazinet 2004). To produce demineralized and delactosed WPC, crystallization and separation of lactose are performed prior to demineralization by ED or IE (Henning et al. 2006). Lactose and mineral depleted WPC is evaporated and dried to produce whey protein powder.

nonprotein nitrogen (Hausmann et al. 2013; Jelen 1979). Whey has previously been regarded as a waste by-product in cheese making, but due to the high organic content of whey, disposal to the environment led to environmental and health issues where it added a nutrient burden to natural waterways and facilitated the growth of infectious organisms. With the introduction of membrane technologies to the dairy industry over the last three decades, whey waste is now cost-effectively processed into valuable products and is an example of how an industry has successfully dealt with a waste problem in a commercially viable way. Products that utilize whey include body-building formula, while other examples include its use as a food ingredient, for example, whey proteins replacing egg proteins in confectionary and bakery products and milk in ice cream and other dairy products.

Whey Processing: Overview and Role of Membranes

Whey Production, Its Composition, and Market Value

Whey is the by-product of the manufacture of cheese, which can vary depending on the type of cheese. For example, whey can be found in “sweet,” “acid,” and “salty” forms depending on what type of cheese is being produced or where in the production the whey is removed (Ramchandran and Vasiljevic 2013). Whey can be generally regarded as milk without casein and fat (Daufin et al. 2001). An example of solids in whey (i.e., non-water components) consists primarily of lactose (75–80 %), minerals (9–10 %), and whey protein (8–11 %). The remaining components in whey include fat, casein, and

Overview of Membranes for Whey Processing

Membrane technology has played a major role in the development of modern dairy processing. Forty percent of all membranes used in the food industry are for dairy application (Daufin et al. 2001). The majority of the membranes in dairy are used for whey processing (Pouliot 2008). The membranes have been applied in numerous roles including producing desired products of reliable quality or even extracting specific proteins (Henning et al. 2006). However the focus here is in whey processing. The membrane technologies that can be used to process whey involve every type of membrane filtration size classification: microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO). The majority of membranes used in whey processing are UF and RO, where UF is the most popular (Pouliot 2008). Figure 1 shows the simplified flow diagrams of how membrane operations function in whey processing. Each type operates to fractionate the core components of whey in the order of fats (MF), proteins (UF), lactose (NF), and minerals (RO). Because RO removes water, it is applied on both the concentrate of UF and the permeate of NF.

Membranes come in a wide range of materials and geometries. Materials include polymeric, ceramic, and metallic. The geometries include tubular, hollow fiber, and flat sheet. Flat-sheet membranes are usually configured into spiral wound and plate and frame modules. Spiral wound membrane modules are the most common in whey processing and are predominantly made of polymeric materials. Polymer membranes are low cost and compact. Ceramic membranes are also popular in dairy processing due to their food compatibility, long life, and unique narrow pore size distribution giving them the ability to target specific components which are desired to be separated. Each filtration operation is described in the following sections.

Whey Microfiltration

MF is commonly applied in dairy processing as a means to remove fat globules but also has a function to remove microorganisms as small as bacteria for extending shelf life of dairy products (Daufin et al. 2001). MF is defined by its pore size ranging from 0.1 to 5 μm . For fat separations, MF can be chosen based on pore size to fractionate large and small fat globules being of use in various dairy products. For bacteria removal, a

membrane with pore size of 1.4 μm can retain 99.0 % bacteria, while casein transmission is 99 %. The application for processing whey as shown in Fig. 1 (bottom train) has been proposed using ceramic membranes for removing fats to prevent fouling of the downstream UF membrane (Golbandi et al. 2013). This allows for higher protein concentrations to be achieved by UF (Ramchandran and Vasiljevic 2013). MF can also be used to produce sweet whey from skim milk as shown in the top train of Fig. 1. Ceramic MF membranes with pore size of 0.1 μm can be used to process skim milk, producing a product having similar composition to sweet whey. Aside from the process trains in Fig. 1, MF can also be used to concentrate native caseins which are used in the cheese-making process (e.g., for its excellent rennet-coagulating properties). It is this ability for MF to reduce the ratio of whey proteins to caseins in cheese milk that is gaining attention due to its ability to improve yield of cheese, particularly hard cheese varieties.

Whey Ultrafiltration

UF is defined in terms of its pore size, which ranges from 0.001 to 0.5 μm (Pouliot 2008). UF is one of the most commonly used membrane

Whey Processing: Overview and Role of Membranes,

Fig. 1 Membrane filtration operations used in cheese making or whey processing. *Top train* gives an example of MF to produce a permeate resembling sweet whey. *Bottom train* gives an example of whey-processing membrane filtration operations

processes used in dairy and will be presented in more detail in the next section “[Whey Ultrafiltration](#).” Its primary function in whey processing is to concentrate whey proteins, leading to whey protein concentrate (WPC), being a valuable product in many markets.

Whey Nanofiltration

NF is a newer membrane separation to industry, which has the ability to enable minerals to pass but concentrate larger organic molecules. Its pore size is in the range of 0.1–1 nm (Pouliot 2008) which is in the size range of small molecules and minerals. In some types of NF, minerals can be fractionated (i.e., passing monovalent salts like sodium chloride but blocking multivalent salts like calcium phosphate). However, as shown in Fig. 1, a common application in whey processing is to process UF permeate. The UF permeate, depleted of fats and proteins, is processed by NF to concentrate lactose and permeate minerals. The concentrated lactose fed to lactose crystallizers increases the lactose yield (Daufin et al. 2001). NF application in demineralization will be discussed in more detail in the section “[► Whey Demineralization with Membrane Operations](#).” Another application of NF is in the conversion of acid whey into sweet whey involving pH adjustment and diafiltration (Pouliot 2008).

Whey Reverse Osmosis

RO can be regarded as concentrating essentially everything and permeating only water, which means it blocks essentially all the smallest molecules in solution corresponding to a pore size of <0.1 nm (Pouliot 2008). In dairy processing, RO is regarded as a dewatering operation that is less energy intensive than evaporative techniques. RO is mostly used for whey concentration (Daufin et al. 2001). Here, whey is concentrated up to 27 % dry matter at which osmotic pressure of the whey becomes limiting and must be passed to an evaporative process if continued drying is needed. RO also becomes limiting at high dry matter

concentrations due to high viscosity, lactose crystallization, and calcium phosphate precipitation. The ability to extend this limit for whey processing has been explored with membrane distillation, where energy and performance advantages could be realized due to lower pressure required (Hausmann et al. 2014). RO can also be applied to treat NF permeate as shown in Fig. 1. Here, most organic matter has been removed and the RO operates to concentrate dairy minerals. No significant market has been found for dairy minerals concentrated by RO, so at present the RO is useful to reduce the volume sent to brine lagoon as a sewer or ocean outfall is not convenient or viable at the site the dairy plant is located. As shown in Fig. 1, RO can also be used on the UF concentrate to dewater the proteins prior to drying, which can save energy as thermal processes utilize much more energy overall than RO.

Electrodialysis

Electrodialysis (ED) is an electrochemical separation process where ionic species are transported from one solution to another under the influence of an electrical charge. In migrating from the solution, the ions pass cationic and anionic membranes, giving the process the ability to demineralize the incoming solution. ED is used in food processing to concentrate, purify, or modify foods (Bazinet 2004). The key distinction of ED to MF, UF, NF, and RO is that ED uses an electric field as the driving force for separation, thus selecting species having charges. The other operations worked principally on size exclusion and require pressure as the driving force. ED is a well-known process in dairy processing, having roles including demineralization, deacidification, acid production, and enriching protein fractions. Demineralization of whey is an important application of ED, as the mineral salts affect the flavor, functionality, and value of whey products. This will be explored in more details in the section “[Whey Demineralisation and Membrane Operations](#).”

While not shown in Fig. 1, ED is applied in various locations in whey processing train. It can

be applied to both the permeate and concentrate of UF, but work appears mostly done by researchers and little application in industry (Bazinet 2004). In the application to UF concentrate, ED can have an important role in the production of whey protein concentrate. The concentrate is demineralized by ED and mixed with lactose and nonfat milk solids to produce infant formula. In the application of deacidification, ED can be used to remove organic acid (e.g., lactic acid) produced during the fermentation of whey. More details of this aspect of whey processing can be found in the literature (Bazinet 2004).

Due to the ever-increasing production of cheese varieties, the generation of whey, as a consequence, results in the separation, fractionation, and concentration of valuable whey components, mainly proteins, while other components such as lactose and specific minerals are also extracted and used in different industrial applications. The estimated world's whey protein production exceeds 770,000 metric tonnes annually (Thompson et al. 2009). The composition of whey protein products usually varies depending on the method of casein concentration. The whey resulting from rennet-coagulated casein or rennet-type Cheddar or Swiss cheese manufacturing is known as sweet whey (pH >5.6). It contains higher lactose content than acid whey, which is obtained from the manufacture of acid casein brought about by addition of either lactic or mineral acid. It also contains more mineral (ash) content comparatively. Once a major pollutant, whey has now been recognized as a source of a diverse range of products including whey powder, sweet whey, demineralized whey, deproteinized whey, nonhygroscopic demineralized whey, reduced lactose whey, lactose, whey protein concentrates, whey protein isolates, and a range of different individual proteins with various physical and physiological functionalities. Based on this list, whey-based products may be grouped into three classes – basic products (whey products and variants), value-added products (whey protein concentrate and isolate), and specialized products (lactoperoxidase, lactoferrin, whey

protein-derived peptides, and nutraceuticals) (Kilara 2008). Value-added whey products are protein-enriched fractions containing from 25 % to over 90 % of proteins. The nonprotein fraction is composed of water and varying concentration of lactose, minerals, minute amounts of lipids, and likely organic acids produced during metabolic activity of cheese starter cultures. The overall functionality of concentrated whey proteins depends on the initial composition of whey. Whey proteins are a complex mixture of various proteins present in different concentrations. The bovine whey is composed of β -lactoglobulin (β -Lg), α -lactalbumin (α -La), bovine serum albumin (BSA), immunoglobulins (Ig), proteose peptones, and some other minor proteins including lactoperoxidase, lysosome, and lactoferrin. β -Lg is the most abundant whey protein with the molecular weight of ~ 18.3 kDa with the primary sequence composed of 162 amino acids. Its isoelectric point is $\sim$ pH 5.2 representing ~ 50 % of total whey proteins and also ~ 12 % of total milk proteins. Ten genetic variants of bovine β -Lg have been identified so far (Fox and McSweeney 2003); however, the two common variants with equal frequency are β -Lg A and β -Lg B, which differ from each other only in two amino acids, resulting in a significant difference in their solubility (de Wit 2009). The next important variant is variant C, identified in Jersey cows. Depending on the positioning of different amino acids and salt bridges on the protein, the heat stability of these β -Lg genetic variants differs. For example, at low temperatures, variant A is less stable than variant C as opposed to stability at higher temperatures, at which variant A is more stable than variants B and C due to its better hydrophobic packing. The major features of the secondary structure of β -Lg are two antiparallel β -sheets formed by nine strands labeled A to I, and eight of them form somewhat flattened β -barrel, which covers the thiol group of Cys₁₂₁ with the help of α -helix that is situated parallel to strands A, F, G, and H. Furthermore, one side of both the β -sheets is hydrophobic, and the hydrophobic sides face each other forming a highly hydrophobic cavity

(Considine et al. 2007). The stability of the ternary structure of β -Lg is strongly depending on the two disulfide bonds positioned between Cys₆₆-Cys₁₆₀ and Cys₁₀₆-Cys₁₁₉ (Thompson et al. 2009). They are available as dimers between pH ~ 3 and ~ 7.5 , and as a result, at natural pH they exist as stable non-covalent dimers at room temperature, but beyond that temperature they dissociate to monomers. α -La represents ~ 20 % of total whey proteins and ~ 3.5 % of total milk proteins. It is composed of 123 amino acid residues with the molecular weight of ~ 14 kDa and the isoelectric point of $\sim$ pH 4.8. Two genetic variants of α -La have been identified as A- and B- (Fox and McSweeney 2003). This globular molecule has split into two as an α -lobe, which contains three α -helices (about 26 %) and two short helices, and a β -lobe that contains small three stranded β -sheets (about 14 %) and a short helical structure; however, 60 % of the protein is unordered (Thompson et al. 2009). In the native form, α -La is a monomer with four disulfide bridges between the amino acid residues of 6 and 120, 28 and 111, 61 and 77, and 73 and 91. However, the disulfide bond between Cys₆ and Cys₁₂₀ is more sensitive to be affected than the other three due to its lower inherent stability (Considine et al. 2007). Meanwhile, the absence of thiol groups in the molecule makes it somewhat heat stable. It has a stable configuration between pH 5.4 and 9 (Fox and McSweeney 2003). In addition, it has a Ca²⁺-binding site located in the cleft of two lobes via Asp residues, and Ca also promotes the unfolding of α -La, which means, again, the promotion of heat stability and also recovery of the native conformation. α -La is the most heat stable of the main WP (Fox and McSweeney 2003). Proportionally the third largest whey protein, bovine serum albumin (BSA), consists of 582 amino acid residues with a molecular weight of ~ 66 kDa. Its isoelectric pH is ~ 5.3 . The protein has a multi-domain (three) structure with complex ligand-binding ability. The domains are stabilized by 17 intramolecular disulfide bonds and one free thiol group at Cys₃₄ residue (Thompson et al. 2009). It does not contain any β -sheet; instead it is composed of mainly

Whey Protein Concentrate: Overview and Membrane Operations, Table 1 Compositional range of commercially available whey protein concentrates and isolates (Foegeding et al. 2011)

Product	Protein (%); DM	Moisture (%)	Lactose (%)	Fat (%)	Ash (%)
WPC-35	34.0–36.4	2.9–4.0	47.0–56.0	2.5–4.0	1.6–8.0
WPC-80	72.9–82.8	3–5.2	0.15–7.4	1–10	2.5–11.0
WPI	90–95	4–6	0.2–2.0	0.2–1.5	0.3–4.5

helix, turn, and extended chains (Considine et al. 2007). The C-terminal region of the molecule is more compact than the N-terminal region, and the different domains show differences in hydrophobicity, net charge, and ligand-binding properties. Among the minor whey proteins, lactoferrin, lactoperoxidase, and immunoglobulins at present have a substantial commercial importance. Lactoferrin (LF) is an 80 kDa iron-binding glycoprotein and consists of about 700 amino acid residues (González-Chávez et al. 2009). In comparison to other whey protein fractions, LF has the highest isoelectric point of 8.0, which means that it carries a positive charge at the physiological pH. It is a simple polypeptide chain folded into two symmetrical lobes (N and C lobes), which are highly homologous with one another (33–41 % homology). LF possesses a greater iron-binding affinity and is the only transferring with the ability to retain this metal over a wide pH range, including extremely acidic pH (González-Chávez et al. 2009). Lactoperoxidase is a heme-containing glycoprotein, containing 608 amino acids with a molecular mass of approximately 78 kDa. The heme group in the active site is covalently bound to the enzyme. The enzyme is stabilized by a calcium ion (Bootsa and Floris 2006). The heme group in the catalytic center of the LP molecule is a protoporphyrin IX, covalently bound to the polypeptide chain through an ester bond. The iron content of LP is 0.07 %, corresponding to one iron per LP molecule. Lactoperoxidase is a basic protein with a high isoelectric point of 9.6 (Seifu et al. 2005). Immunoglobulins (IgGs) are a complex group of proteins comprising IgG, IgA, and IgM. These are major proteins present in the colostrum accounting for 10–15 % of the whey protein and at least 2 % of the total milk protein. Immunoglobulins are glycoproteins and are either monomers or

polymers made up of two light chains (~20–25 kDa) and two heavy chains (~50–70 kDa) linked together with disulfide bonds (Harper 2000).

Whey is a dilute solution of lactose (~5 %) and minerals (~0.6 %), colloidal dispersion of whey proteins (~0.6 %), containing also some lipids and some other several constituents at trace levels (Fox and McSweeney 2003). Considering the composition of concentrated whey protein products (Table 1), it is obvious that substantial amounts of water need to be removed in order to produce products of required properties. For example, the United State Code of Federal Regulations defines whey protein concentrate as “the substance obtained by the removal of sufficient nonprotein constituents from whey so that the finished dry product contains not less than 25 % protein. Whey protein concentrate is produced by separation techniques such as precipitation, filtration, or dialysis. As with whey, whey protein concentrate can be used as a fluid, concentrate, or dry product form. The acidity of whey protein concentrate may be adjusted by the addition of safe and suitable pH-adjusting ingredients.” Depending on the required functional properties, a variety of membrane processes in conjunction with traditional food processing and more sophisticated chromatographic methods can be employed. In general, four membrane technologies are used in whey protein concentration including microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO). With the realization that the separation of whey into well-defined fractions with specific functionalities would enable optimal use of whey and result in novel product formulations, newer membrane-based processes have been introduced. For example, the electrically driven membrane processes used are electrodialysis and

Whey Protein Concentrate: Overview and Membrane Operations, Fig. 1 Schematic diagram of production of whey protein concentrates

electrodeionization. While the main adsorption technique employed has been ion exchange, with advances in development of new technologies, affinity binding and some other approaches with commercial limitations have been employed. Traditional food processing such as the application of heat may be used at various stages of processing. As a consequence, various whey protein products may have the same protein content but vary in composition of nonprotein compounds, which would in turn impact on their food applications (Fig. 1).

Most commercial WPCs contain either 34–35 or 80 % protein (Table 1). This ingredient is used as a substitute for nonfat dry milk (NFDM) or skim milk powder in the manufacture of yogurt and infant formulae and in various bakery products. WPC-35 is also used in production of stews and sauces due to their thickening behavior in addition to their nutritional benefit. In general, whey is clarified and defatted and thermally treated and then subjected to ultrafiltration. The

resulting permeate mainly consists of lactose and some minerals. The retentate, which now contains almost an equal part of lactose and proteins, may first be further concentrated by evaporation but in many instances is simply spray-dried. The main characteristic and thus performance of this product are based on its composition; high lactose (over 50 %) and mineral contents impact on the behavior of whey proteins in various food applications. Additional removal of lactose and minerals by application of diafiltration results in whey protein concentrates with a greater concentration of proteins. This process basically presents “washing” of nonprotein constituents by diluting retentates by equal amount of water and further ultrafiltration. Depending on the number of diafiltration steps, a range of protein concentrations may be achieved, which would have different industrial application. WPCs containing 80 % protein are usually intended for applications in which proteins play a dominant functional role, such as gelation, emulsification, and foam

formation. Very low lactose content of this WPC makes this product a desirable product for sports nutrition and weight management products.

Further compositional adjustments or manipulations may take place to produce products with required physical properties. For the successful utilization of functional properties of whey proteins in different food systems, they should be recovered in their native, undenatured state and subsequently incorporated in heterogeneous food matrixes. Although chemical and enzymatic modifications of whey proteins are widely applied, they have certain limitations. The application of ultrasound for short duration of time to breakdown protein aggregates formed due to preheating treatments and to prevent reformation of aggregates and the consequent viscosity increase are also in current interest of research (Ashokkumar et al. 2009). In addition, the use of mechanical forces under isothermal and/or isobaric conditions has a significant potential to modify whey proteins (Dissanayake 2011). One of such popular approaches is extrusion, where proteins are thermally denatured under high-pressure conditions technically known as thermoplastic melt. The denatured proteins become fiber form as a result of the process, and sudden release of pressure evaporates water and expands the product. This method has been employed for years and used to produce low-moisture food products such as snacks and breakfast cereals. Another approach termed microparticulation has been used commercially to create whey protein-rich products with enhanced solubility at high temperatures (Dissanayake 2011).

Milk is defined as the secretion of the mammary glands of mammals with the primary function to satisfy nutritional requirements of neonates. Milk of some animals, especially cows, buffaloes, goats, and sheep, is used for human consumption, either as such or in the form of a range of dairy products. Milk may also be defined as a true solution of lactose and minerals, colloidal dispersion of milk proteins, and emulsion of milk fat. Fat globules are dispersed into the serum phase of

Whey Protein Fractionation: Overview and Membrane Operations, Table 1 Composition of milk of main mammalian species (Kailasapathy 2008)

milk. Milk proteins are grouped into two main classes – caseins and whey proteins, which are obtained by acid or rennet-induced coagulation of casein and their removal from the serum. The milk serum, basically devoid of caseins, is commonly termed the whey. Depending on a source (Table 1), composition of milk and thus the whey varies.

Most serum proteins are globular with relatively high hydrophobicity and compact folding. Most of them have a fairly variable secondary structure with a proportion of α -helix and β -sheet. They readily denature at pH values below 6.5 during heating of milk. The denaturation of these proteins in milk does not result in aggregation but in complex interaction with the casein micelles, changing their chemical and physical properties. The main whey proteins are β -lactoglobulin, α -lactalbumin, bovine serum albumin, immunoglobulins, and some minor proteins including lactoferrin and lactoperoxidase. β -Lactoglobulin is the major serum protein, and due to its proportion in the whey, it tends to dominate the properties of whey protein preparations, especially the heat-induced reactions. Its solubility strongly depends on pH and ionic strength, but it remains soluble upon acidification of milk. Due to its importance, the secondary and tertiary structures of β -lactoglobulin have been well characterized. It has two $-S-S-$ bonds and one free sulfhydryl group, which is buried inside the molecule in the native state. The protein undergoes substantial changes in tertiary and quaternary structure with changes in pH or temperature (Kailasapathy 2008). In milk, it is present as a dimer with a molecular weight of approximately 36 kDa. Both molecules are tightly bound to each other, mainly by hydrophobic interactions which

dissociates at high temperature. Below pH 5.5, β -lactoglobulin associates to form an octamer. At even lower pH values, i.e., below 3.5, the proteins appear as a monomer, which is also the form it takes above pH 7.5. β -Lactoglobulin has a tendency to bind some apolar molecules likely due to its hydrophobicity. α -Lactalbumin acts as coenzyme in the synthesis of lactose. It is a small, compactly folded protein with more or less spherical molecule. It appears as a monomer, stable across wide range of conditions but would start to associate at a higher ionic strength. Bovine or blood serum albumin is a minor protein that gains entrance to milk by leakage from blood serum. It is a large molecule with three globular domains, resulting in an elongated shape. It has 17 disulfide bonds and an unpaired thiol group. Immunoglobulins are antibodies synthesized in response to stimulation by specific antigens. These are large glycoprotein molecules with a heterogeneous composition due to their excretion by different secretory cells. In addition to these proteins found in the milk whey, the whey obtained after production of rennet cheese often contains glycomicropeptide (GMP).

Each of these proteins or group of proteins has been proven or implied to have unique physical or physiological (nutraceuticals) functional properties. Some suggested nutraceutical properties include digestive function (β -lactoglobulin), prevention of caries and induction of satiety (GMP), anticarcinogenicity and sleep enhancement (α -lactalbumin), immunomodulation (lactoferrin, lactoperoxidase), and passive immunity (immunoglobulins). The high content of cysteine in α -lactalbumin appears to improve the immune system, while a high level of tryptophan may help improve mood, sleep, and cognitive performance (Foegeding et al. 2011).

This protein also has a high affinity for minerals, specifically calcium, magnesium, zinc, and cobalt. Through this binding, these minerals are more readily delivered for absorption in the human body. Furthermore, α -lactalbumin is the principal protein of human milk, thus adjusting proportion of the major whey proteins, or completely removing β -lactoglobulin, is a regular practice in manufacturing of infant formulae. GMP, which is a soluble peptide due to attached sugar moiety, *N*-acetylneuraminic acid or commonly known as sialic acid, has various unique characteristics in comparison to other whey proteins. Sialic acid may influence digestive function and promote the growth of probiotics. Suggested applications of GMP include beverage, nutritional bar, dietary supplements, diet foods, and pharmaceutical products (Foegeding et al. 2011). Lactoferrin was originally perceived as an iron-binding protein with antimicrobial properties; however the evidence is mounting showing other important physiological roles including regulation of iron homeostasis, host defense against a broad range of microbial infections, anti-inflammatory activity, regulation of cellular growth and differentiation, and protection against cancer development and metastasis (Seifu et al. 2005). Lactoferrin is used in infant formulae, nutritional foods and supplements, sports nutrition supplements, and pharmaceutical products. Lactoperoxidase (LP) is produced by the secretory epithelial cells and acts as an enzyme and a natural antimicrobial agent. LP is used in nutritional products and personal care products (such as mouthwash, skin creams, and shampoos) (Tamura 2004).

The whey protein products are typical in the sense that they are highly heterogeneous in nature and functionality of these products is combined functionalities of individual fractions. Some of the fractions such as LF and LP are present in such a low concentration which creates additional problems in terms of investment and process establishment. In addition to this, the composition of whey varies largely due to variations in milk composition and different methods of cheese manufacture of cheeses, subsequently carrying this variation into whey protein products. Fractionation of whey proteins into pure/enriched products

enables the unique properties of these novel protein fractions to be realized. The development of advanced and novel processing technologies for fractionation of the whey proteins allows for proper utilization of the large quantities of underutilized whey proteins. Protein fractionation refers to the separation and isolation of individual proteins from a multicomponent mixture of proteins. Commonly used methods for fractionation of proteins are salt, heat, and pH treatments (denaturation properties), electrophoresis, ion exchange, affinity chromatography (ionic nature), dialysis, gel permeation, size-exclusion chromatography (differences in size), and complexation (chemical and enzymatic reactivity).

Proteins contain hydrophilic amino acids on their surface, which interact with water molecules and thus stabilize them in water. Based on the differences in solubility, proteins can be fractionated by selective precipitation using salt, temperature, and pH. When salt concentration of a solution exceeds a critical limit, the water is being displaced from the protein thereby leaving the protein dehydrated, the condition known as salting out. Commonly used salts for salting-out purpose are ammonium sulfate, sodium chloride, and potassium chloride. Generally a two step process is used in the salting out of proteins. Initially salt concentration is adjusted just below the level needed for precipitation. The protein mixture is centrifuged to remove precipitated protein followed by bringing the salt concentration to slightly higher than the level required for precipitating the protein. This further precipitates the protein of interest, leaving the more soluble proteins in solution. The main limitation of this method is that the separated protein is contaminated with large quantities of salt and purification of the precipitate may be costly.

Another method used to fractionate proteins is isoelectric focusing, which uses isoelectric pH (pI) to induce protein precipitation. Taking advantage of differences in pI, the isoelectric focusing separates a mixture of proteins into their individual fractions. Recently Bonnaille and Tomasula (2008) reviewed several methods for isolating the whey proteins using salt, heat, and pH treatments. β -Lactoglobulin, BSA, and α -lactalbumin were

Whey Protein Fractionation: Overview and Membrane Operations, Fig. 1 Fractionation of α -lactalbumin (Mulvihill and Ennis 2003)

fractionated using sodium sulfate at pH 6. Chemicals such as ferric chloride, polyphosphates, and sodium chloride have been also used. In fractionation using heat and pH adjustments, the driving force is thermal stability of the whey proteins under acidic conditions. For example, thermal aggregation and separation of α -lactoalbumin are possible by acidification with super critical carbon dioxide (Bonnaille and Tomasula 2008). Another approach for recovery of α -lactoalbumin has been described by Mulvihill and Ennis (2003). When whey is heated, the whey proteins readily unfold exposing their otherwise buried sulfhydryl and hydrophobic sites, thus inducing protein–protein interactions. The extent of denaturation and aggregation is governed by energy density, pH, and concentration of Ca and on the commercial scale would be also influenced by composition of whey (Fig. 1). α -Lactoalbumin is thus precipitated by centrifugation and may be washed to remove excess of lactose and minerals, all of which may result in a high, up to 90 % of protein, purity. This

method has been improved by incorporation of microfiltration, which replaces centrifugation. Separated α -lactoalbumin is further washed and purified by ultrafiltration.

Another method for protein fractionation is adsorption chromatography, which involves selective adsorption–desorption of protein components on a solid matrix (resin) packed in a column. When a multicomponent mixture of proteins is passed through the column, based on differences in affinity to the solid matrix, some proteins adsorb on the solid matrix while the remaining components pass through the column. Ion-exchange chromatography is the most commonly used technique for protein fractionation and is based on reversible adsorption–desorption of proteins to a solid matrix. The molecules bound to the matrix are eluted using solutions of different ionic strength and/or pH of the buffer. Ion-exchange chromatography has been in use for production of WPI. This process is also used in the production of low-salt and low-fat WPC 80, LF, and LP. With careful selection of resin, α -lactoalbumin and β -lactoglobulin can be

fractioned using ion-exchange principles (Mulvihill and Ennis 2003). Minor whey proteins such as LP and LF are mainly isolated due to growing interest into their physiological functionality. LF and LP are positively charged at neutral pH while all other whey proteins have a negative charge; thus this difference has been used in their fractionation. Similar approach has been used for extraction of immunoglobulins and GMP. Another possible approach is to increase molecular size of these components, namely, GMP, by cross-linking using an enzyme, transglutaminase. In this approach cross-flow microfiltration with ceramic membranes was used to remove cross-linked GMP. Due to cross-linking, the particle size was increased enabling separation of GMP from other whey proteins using a 0.1 μm pore-size membrane at 0.4 bar transmembrane pressure and 55 °C (Tolkach and Kulozik 2005).

Affinity chromatography uses highly selective ligands that have reversible affinity for a particular protein. When a multicomponent mixture of proteins is passed through the column, certain proteins are attached to the ligands while the remaining protein fractions pass directly through the column. The protein bound to the ligand is eluted using a buffer solution which favors desorption from the column. Affinity separation is the most efficient means of separating the individual proteins from a mixture. It is very expensive and is not commonly used for commercial scale separations.

Fractionation and concentration of whey proteins from whey is one of the more successful industrial applications of ultrafiltration (UF). However, due to flux decline during operation, the practical limit for whey concentration by UF in modern plants is around 24 % total solids, with a protein to total solid ratio limit of ~0.72:1 (Mulvihill and Ennis 2003). Diafiltration is thus employed to achieve a higher protein to total solid ratio, ~0.80:1, with a total solid content of approximately 28 %. However, the efficiency of UF in whey processing is limited by several factors, the most significant of which are concentration polarization and membrane fouling (Rao 2002). Both factors adversely affect permeate flux, which may also be aggravated by protein–protein and membrane–protein interactions (Lipnizki 2005). These impacts however may be minimized by choosing suitable membrane material and configuration as well as

the appropriate process conditions such as trans-membrane pressure, feed velocity or recirculation rate, temperature, and composition including pretreatment of whey (Cheryan 1998). Opposing charge on the whey proteins and the membrane induces protein–membrane electrostatic attractions initiating protein adsorption on the membrane surface (Lipnizki 2005). This may result in the undesirable protein unfolding, denaturation, and aggregation especially at high-shear operations (Cheryan 1998). The polymeric polysulfone membrane has been the most widely used membrane in whey UF mainly due to its low cost, good thermal stability, and mechanical properties (Brans et al. 2004). The main problem with the use of the hydrophobic polysulfone membrane in the whey processing in comparison to ceramic or hydrophilic polymeric membranes is associated with greater attraction between the membrane surface and the proteins through the hydrophobic and electrostatically induced interactions resulting in severe fouling and flux retardation (Brans et al. 2004). Today ceramic membranes are gaining more attention because of their greater resistance against cleaning and disinfection.

Due to abovementioned limitations, whey protein isolates are manufactured commercially by one of two fundamentally different processes – microfiltration followed by ultrafiltration or ion exchange (Neville et al. 2001). These two processes use completely different methods to isolate the valuable proteins that are present in low concentrations in cheese whey. Microfiltration is a key step during concentration. The pore size of the membrane is selected to capture all the residual fat, particulates (i.e., denatured protein), and microbial debris, while allowing the soluble protein and all

the other components (e.g., lactose, minerals) to pass through unhindered. This prevents membrane fouling in the following steps. The clarified material forms the feed to the second membrane-processing step, ultrafiltration. This process produces a WPI that differs from the ion exchange analogue in that there is no chemical modification of the protein, and the glycomacropeptide, normally released during production of rennet type cheeses, is retained in the product. If no pH adjustment is used and the process is carried out under mild temperatures, the final product is almost completely free of denatured material.

Whey proteins due to their diversity are not defined by a single isoelectric point. The isoelectric point of the major proteins varies from 4.8 to 5.2, while some minor proteins have an alkaline isoelectric point. This means that by adjusting pH, it is possible to first remove minerals and then produce whey protein isolates of different compositions (Table 1). Proteins in general have a positive and a negative charge below and above their isoelectric point. At pH values above their isoelectric point, proteins behave as anions that can be adsorbed on anion exchangers. Therefore, protein molecules are removed from liquid whey through chemical binding to specially developed resins, across which the whey flows. The binding is reversible via pH adjustment, and the protein in the eluted material is subsequently concentrated via ultrafiltration. For example, “Vistec” process uses a cellulose-based exchanger in a stirred tank reactor (Mulvihill and Ennis 2003) (Fig. 1). During this process, whey is acidified to pH <4.6, pumped into the reactor, and stirred to allow adsorption of proteins onto the ion exchanger. Soluble material including lactose and minerals

Whey Protein Isolation: Overview and

Membrane Operations,

Fig. 1 Production of whey protein isolate through ion exchange process (Mulvihill and Ennis 2003)

is removed with water, while proteins remain adsorbed onto the resin. The resin is then resuspended in water followed by pH adjustment to >5.5 , which results in protein separation due to changed charge. The proteins are then separated from the resin by filtration and consequently concentrated by ultrafiltration. Another process, “Spherosil,” uses either cationic Spherosil S or anionic Spherosil QMA ion exchanger for fractionation in a fixed-bed column reactor (Mulvihill and Ennis 2003). Similar to the process above, pH of the whey is adjusted, and it is pumped into the column where the proteins are adsorbed onto the surface, while all other unadsorbed material (lactose) is eluted with water. Under ideal operating conditions, over 85 % of the proteins can be recovered (Mulvihill and Ennis 2003). After elution, the released proteins are concentrated and spray-dried (Fig. 1). Due to their high protein purity and solution clarity, WPIs are extensively used as nutritional supplements in sports and health drinks and in protein-fortified beverages. The high protein content improves WPI physical functionality including water binding, gelling, emulsifying,

and foaming. While obviously composition of WPIs can be manipulated during their production, pH can additionally be altered prior to drying, creating a WPI with an acidic pH, primarily designed for use in acidic beverage applications.

History and Application of Ultrafiltration

Ultrafiltration (UF) of whey is common in dairy processing. It was the first membrane application to dairy processing, which commenced in the 1970s upon the development of sanitary membrane modules (Pouliot 2008). The early installations of UF were used to concentrate milk prior to cheese making and in the recovery of whey proteins. In the application for whey protein recovery, UF separates the whey complex by blocking whey proteins by size exclusion, leaving the module via the concentrate. The lactose and mineral-rich solution that is removed via passing the membrane leave the module as permeate. In the early applications of UF, the market for the whey protein concentrate (WPC) was small, so a great effort was devoted to finding applications in food systems in the 1980s. The whey proteins are now commercially valuable and are often sold as a nutritional supplement, particularly for the sport of body building, but also as an ingredient in functional or health-promoting foods (Ramchandran and Vasiljevic 2013).

Function of Ultrafiltration and Operation Modes

The function of the UF to remove whey proteins relies on its molecular weight cutoff (MWCO),

which is defined as the lowest molecular weight solute in which 90 % of the solute is retained by the membrane. The MWCO of UF membranes ranges from 10^3 to 10^6 Da. In terms of physical size, the pore size of UF membranes can vary between 1 nm and 0.5 μm (Pouliot 2008). In general, this means UF membranes are highly effective at blocking colloids, macromolecules, and viruses but passing sugars and minerals. The pressure of UF systems ranges from 3 to 10 bar. In a single stage, UF is capable of concentrating whey by 10–30 times that of the feed. To achieve high protein purities, UF can be applied in diafiltration mode, where a solvent (typically water) is added during UF to “wash out” the components that permeate the membrane (Hausmann et al. 2013a). For example, whey protein concentrate (WPC) of 99 % protein purity can be produced when UF is combined with diafiltration (Henning et al. 2006). An obvious drawback of diafiltration is the large volume of watery waste produced.

UF has greatly assisted dairy processors, providing a low temperature equivalent to the traditional costly thermal processes which would alter the texture of the whey and denature proteins. UF membranes used in dairy processing are typically in spiral wound format. Spiral wound membrane modules involve the flat membrane sheets coiled around a central tube to carry out the permeated fluid, which is key to their low unit cost and success of UF in the dairy industry.

Membrane Fouling and Control Techniques

A key issue in UF of whey is membrane fouling, which has the effect of reducing the flux and permeate production in the installed system. Fouling is a complex effect which combines both the effect of flux, as well as the interaction chemistry between the membrane material and the components of whey (Ramchandran and Vasiljevic 2013). In the effect of flux, the selective depletion of lactose and minerals through the membrane causes a steep rise in concentration of the blocked proteins near the surface. This effect is known as

concentration polarization and causes flow resistance and flux decline. Also, all components in the whey will interact with the membrane where strong adsorption can take place which also causes resistance to flux. The interactions however are very complex, and in studies of whey component interactions on hydrophobic polytetrafluoroethylene, the key components responsible for fouling are the whey proteins and minerals (Hausmann et al. 2013b). The role of proteins and calcium phosphate (a dominant mineral found in whey) in interacting with the membrane and then building up the resistive layer was highlighted in a recent review by Koh et al. (2013).

Concentration polarization and surface adsorption are effects that cannot be avoided, but are managed by choosing important features such as membrane material, operation temperature, applied pressure, and crossflow velocity. Despite these control techniques, the membrane still must be cleaned to remove built-up fouling material as well as to disinfect the membrane. Therefore, a cleaning process is carried out to thoroughly clean the membrane and remove any potential biological contaminants. Cleaning can be performed mechanically, hydraulically, electrically, or chemically (Koh et al. 2013). Chemical cleans are most common and are carried out as part of a routine clean-in-place (CIP). Cleaning can be carried out daily as part of the need to disinfect the membrane processes to prevent biological contamination (Zeman and Zydney 1996). The CIP process requires the membrane plant to be put offline for the cleaning to occur. CIP can be carried out with an alkaline solution, such as sodium hydroxide solution, to remove organic matter such as fats and proteins. An acidic clean is also carried out to remove minerals, particularly those which form scale on the membrane like calcium phosphate. Additives can be included in the CIP, such as surfactant, enzymatic, and chelating compounds, to facilitate cleaning. The choice of which will depend on the specific chemistry of the fouling, for example, enzymatic cleaners can be used to remove proteinaceous fouling. If cleaning cannot restore the membrane flux, or the membrane has been degraded in time leading to lost rejection, the membrane requires replacement. The lifetime of

the membrane in dairy applications depends on the membrane material, operation conditions, and severity of cleaning. Generally, polymer membranes are expected to last 1 year, while ceramic membranes will last 5 years.

White Water Recovery by Membrane Operations

Ángeles Blanco, Daphne Hermosilla,
M. Concepción Monte and Carlos Negro
Department of Chemical Engineering,
Universidad Complutense de Madrid, Madrid,
Spain

The water system of a modern paper mill is divided in several water loops where the water is used in countercurrent. A strict separation of loops

White Water Recovery by Membrane Operations,

Fig. 1 Outline of a paper production process (Adapted from The Handbook of Environmental Chemistry: Emerging Challenges in Wastewater Reuse: Contaminants, Treatment, and Effects Blanco et al. 2015)

is required to minimize transferring detrimental substances from more contaminated to cleaner circuits. In this way, the paper machine, which addresses the highest water quality requirements, is kept as clean as possible to produce a high-quality final product. Thus, fresh water is just mainly used at critical points such as the wire and press section showers or for the preparation of chemicals.

White water loop or paper machine loop holds the highest flow and best quality standards. It can represent more than half of the total effluent load generated in the mill if it is not reused. The main objective of this loop is to dilute the thick stock within the approach system to about a 1 % consistency (10 g/L) to facilitate the mixing of fibers, fillers, and additives in the headbox and their homogeneous distribution on the paper machine wire. In the wire section, a fiber web is formed and dewatering is performed. The retention of solids on the wire is critical for paper quality, whereas water drainage is a key factor for machine speed; both of which can be controlled by the addition of additives. Conditions on the wire section such as retention, dewatering, and additive performance are decisive regarding white water characteristics.

Later on, in the press section, formed by several press nips, the paper sheet is consolidated, and the dry content of the paper web is increased as much as possible by compression (up to approximately a 40–55 % consistency depending on the product to produce and the raw material and machine that are used) (Holik 2006). Dewatering of felts is performed by suction pipes.

The dewatering water from the wire and press sections is called white water. It is collected, clarified (to recover solids), and reused in the white water's loop. The excess of water is sent in countercurrent to the previous water loop.

Thus, white water is intensively recirculated through the process to minimize water consumption. It is firstly reused in the paper machine primary circuit, which consists in a short loop with the main purpose of diluting the stock within the approach system (Fig. 1). The white water that is drained from the paper machine is firstly clarified in save-alls, mainly by filtration, or other water treatment technologies such as dissolved air flotation. Disk filters are the prime technology used in save-alls, which shows the advantage of being able to produce different water qualities, namely, cloudy, clear, and super clear, corresponding to

their solids content. Furthermore, trouble associated to fouling and energy consumption may be of less importance when implementing membrane technologies. In mills producing high-quality grades with closed water circuits, the BREF (2013) recommends an advanced white water treatment. Membrane processes obtain water of different qualities according to the needs of each process, including high qualities, as required for pressure showers, the preparation and dilution of chemicals, vacuum systems, and sealing water for pumps and agitators (Nuortila-Jokinen et al. 2004; Judd and Jefferson 2005; Kallioinen et al. 2010; BREF 2013).

Different ultrafiltration systems have been implemented to improve the quality of the white water that is reused in the paper machine, such as in Metsä-Serla Kirknemi mills in Finland, Stora Enso mills in Kabel and Utersen, Germany (Nuortila-Jokinen 2003), and PM61 Holmen Paper Madrid (Monte et al. 2011). Besides the need of reducing water consumption, the use of ultrafiltration has been addressed to keep the paper machine cleaner by improving process water quality (removal of solids and microorganisms), to reduce the number of breaks, and to minimize cleaning maintenance (Nuortila-Jokinen 2003; Monte et al. 2011). On the other hand, to further improve internal water use, white water may be recirculated in a secondary circuit, where internal kidneys based also on membrane technologies, biological treatment, evaporation, or ozonation processes, among others, may be implemented.

The performance of membrane systems within paper mills is fully affected by fouling and erosion of the active layer (Monte et al. 2011) because white water usually carries a high amount of suspended solids (mainly fibers), colloidal and dissolved organic matter, and inorganic compounds such as calcium carbonate and silica. The influence of process parameters on water quality is a critical issue to consider in the implementation of membrane systems. Particularly, the performance of the retention system and the use of additives (biocides, cationic compounds, and sizing agents, among others) must be controlled and evaluated during membrane operations as

they significantly affect the characteristics of the resulting white water. Moreover, the level of circuit closure, which is directly related to the contamination level of process water, must remain at a level that may be tolerated to keep the quality of the produced paper and the runnability of both the paper machine and the associated water treatment technologies.

Although microfiltration might have been expected to allow better fluxes for white water treatment than ultrafiltration, these systems could show similar performance problems than ultrafiltration because the foulants that are associated to this type of water (such as bacteria, pitch, and stickies) are of a very similar size to the pores of microfiltration membranes (Hubbe 2007; Kaya et al. 2010).

The treatment of white water by reverse osmosis or nanofiltration systems may produce water of enough quality to be used in the most critical points of the paper machine, such as high-pressure showers; but their use is limited because of the membrane fouling caused by organic and inorganic compounds (mainly calcium carbonate and silica) even when an appropriate pretreatment such as ultrafiltration is complementarily implemented (Kaya et al. 2010; Ordoñez et al. 2010).

Some important general issues considering the use of membranes for white water recovery are any type of membrane filtration cannot handle sudden peaks of suspended solids; high-pressure filtration methods produce cleaner water, but consume more electricity and must be sized larger or equipped with more efficient pretreatment or countermeasures to protect against plugging; pretreatment processes such as chemical coagulation, adsorption, sedimentation, or flotation may be required to reduce the associated problems to membrane fouling (Hubbe 2007); symmetric membranes have a higher tendency to plug, although plugging may be avoided by maintaining highly turbulent conditions, which otherwise will require more energy; and final treatment and disposal of the concentrates must be considered (BREF 2013).

The current tendency to make membrane systems competitive for the treatment of white water

is to develop low fouling membrane processes, such as those systems with higher associated cross flow velocities (e.g. rotation systems) (Monte et al. 2011), or better membrane materials. Characteristics such as hydrophilicity, pore size, surface roughness, and retention capacity have a very important effect on the development of membranes to be used for this application (Kaya et al. 2010).

Wide-Angle X-Ray Diffraction (WAXD)

► Wide-Angle X-Ray Scattering (WAXS)

Wide-Angle X-Ray Diffraction Pattern

Doriano Lamba

Institute of Crystallography, National Research Council, Trieste, Italy

According to the Wide-Angle X-ray Diffraction (WAXD) method, the sample is scanned in a wide-angle X-ray goniometer, and the scattering intensity is plotted as a function of the 2θ angle.

When X-rays are directed in solids, they will scatter in predictable patterns based upon the internal structure of the solid. A crystalline solid consists of regularly spaced atoms (electrons) that can be described by imaginary planes. The distance between these planes is called the d-spacing. The intensity of the d-space pattern is directly proportional to the number of electrons (atoms) that are found in the imaginary planes (Warren 1990).

Every crystalline solid will have a unique pattern of d-spacings, which represents a *fingerprint* for that solid. In fact, solids with the same chemical composition but different phases can be identified by their pattern of d-spacings.

For semicrystalline isotropic materials, a qualitative measure of crystallinity is directly obtained from the respective WAXD curve.

Figure 1 shows the phenomenon for poly(ethylene terephthalate) (PET) membrane (Stribeck 2007). The curve in bold solid line shows a WAXD curve with many reflections. The material is a PET with a high degree of crystallinity. The thin solid line at the bottom shows a compressed image of the corresponding scattering curve from a completely amorphous sample. Compared to the semicrystalline material it only shows two very broad peaks – the so-called first and second order of the amorphous halo.

Wide-Angle X-Ray Diffraction Pattern,

Fig. 1 WAXD curves from semicrystalline and amorphous poly(ethylene terephthalate) (PET). Separation of the observed intensity into crystalline, amorphous, and machine background (laboratory goniometer Philips PW 1078, symmetrical-reflection geometry) (This figure has been taken from Stribeck (2007) (Fig. 8.2, p. 102))

It is obvious that the semicrystalline material contains this amorphous feature as well, underneath the reflections. In the semicrystalline material, the halo is shifted to higher scattering angle. In fact, the dash-dotted curve is simply an image of the scattering curve of the amorphous material stretched in the vertical as well as in the horizontal direction.

The dash-dot-dotted curve shows the *instrumental background* of the goniometer. Identification of the observed peaks can be accomplished by means of data listed in the *Polymer Handbook* (Brandrup et al. 2005).

A simple method can be used to describe changing crystallinity from WAXD data of isotropic materials. It is based on the computation of areas in Fig. 1. At first, the border between first-order and second-order amorphous halo is identified. For PET, this is at $2\theta \approx 37^\circ$ (vertical line in the plot). Then the area, A_{am} , between the amorphous halo and the machine background is integrated. Finally the area, A_{cr} , between the crystalline reflections and the amorphous halo is integrated and the crystallinity index X_c , $X_c = A_{cr}/(A_{am} + A_{cr})$, is computed.

Wide-Angle X-ray diffraction (WAXD)

Wide-Angle X-ray Scattering (WAXS) or Wide-Angle X-ray Diffraction (WAXD) is an x-ray-diffraction technique that is often used to determine the crystalline structure of inorganic and organic polymeric membranes. This technique specifically refers to the analysis of Bragg peaks scattered to wide angles ($2\theta > 1^\circ$), which by Bragg's law implies that they are caused by subnanometer-sized structures.

The Debye's equation (Guinier 1963)

$$I(q) = \sum_{i,j}^N f_i f_j \frac{\sin(qr_{ij})}{qr_{ij}} e^{-2\sigma_{ij}^2 q^2}$$

Wide-Angle X-Ray Scattering (WAXS), Fig. 1 Wide-angle X-ray scattering from (a) polystyrene, showing a diffuse halo from an amorphous sample; and (b) highly

crystalline polyethylene, showing sharp ‘powder’ rings (This figure has been taken from Bower (2002), Fig. 3.9, p. 81)

provides a relationship between interatomic distances r_{ij} and the x-ray scattering factors f_i and f_j of the atoms i and j respectively.

$$q = 4\pi \frac{\sin(\theta)}{\lambda}$$

represents the scattering vector and $e^{-2\sigma_{ij}^2 q^2}$ is the Debye–Waller thermal factor.

σ_{ij}^2 is the atomic mean-square displacement. Thermal motion reduces WAXS intensity.

To derive the equation, it is assumed that the sample is composed of perfect crystals of finite dimensions randomly oriented, each consisting of N atoms that vibrate with harmonic motion. Wider is the motion, greater is the Debye–Waller factor.

The Fourier transform of the reduced intensity $I(q)$ results in a radial distribution and hence provides information about short and medium range order in the sample.

Wide-Angle X-ray Scattering is the same technique as Small-Angle X-ray Scattering (SAXS); only the distance from sample to the detector is shorter and thus diffraction maxima at larger angles are observed. Depending on the measurement instrument used, it is possible to do WAXS

and SAXS in a single run (Small- and Wide-Angle X-ray Scattering SWAXS).

At third generation synchrotron radiation sources, the development of μ -sized beams allows to perform time-resolved μ SAXS/ μ WAXS experiments on polymeric membranes during melting, crystallization, and deformation aiming to visualize and understand the evolution of nanostructures (Stribeck 2007; Nozue et al. 2007).

Amorphous structures yield scattering halos (broad peaks) whereas crystalline structures are characterized by Bragg peaks (Fig. 1). WAXS is therefore a good monitor of crystallinity in the sample.

This technique is a time-honored but a somewhat out-of-favor technique for the determination of degree of crystallinity of inorganic and/or organic membrane polymeric samples. The diffraction pattern generated allows to determine the chemical composition or phase composition of the membrane film, the texture of the membrane film (preferred alignment of crystallites), the crystallite size, and presence of film stress.

According to this method, the sample is scanned in a wide-angle x-ray goniometer and the scattering intensity is plotted as a function of the 2θ angle.

Wine Aroma Enhancement

Johannes De Bruijn

Department of Agroindustry, Food Engineering Group, Universidad de Concepcion, Chillan, Chile

Aroma-A primary wine aroma refers generally to a pleasant smell of fruity, floral, herbal, mineral, and/or woody flavors of young wine, unique to each grape variety, which will be interpreted by the olfactory bulb. Secondary wine aromas are those flavors that arise from the chemical reactions during fermentation and aging in barrels, while tertiary aromas are those smells that are developed by aging in the bottle. The term bouquet generally refers to both secondary and tertiary aromas, while the term odor is related to an unpleasant smell due to possible wine faults.

The typical aroma of wines is mainly due to volatile compounds that come from the grape. Apart from free flavor compounds, a significant part of several aroma compounds is accumulated in the grape berry as odorless nonvolatile glycosides. Odorous volatiles come available after acid or enzymatic hydrolysis from glycosides during wine storage, arise after aging on lees or micro-oxygenation, and can be enhanced by membrane technology.

The glycosylated aroma fractions that can give rise to odor-active compounds upon

hydrolysis include monoterpenes (e.g., linalool, nerol, geraniol, α -terpineol, and citronellol), benzenoid compounds (e.g., phenol, guaiacol, 4-vinylguaiacol, and 4-vinylphenol), norisoprenoids (e.g., damascone, 3-hydroxy damascone, and enyne diol), and aliphatic alcohols (e.g. 3-methylbutanol). Acid hydrolysis occurs quite slowly in winemaking conditions. Moreover, exogenous glycosidases (β -glucosidase, α -rhamnosidase, α -arabinosidase, and β -apiosidase) from yeast and filamentous fungi may be used for enzymatic hydrolysis of mono- and diglycosides to enhance wine aroma (Cabaroğlu et al. 2003). Wine aroma quality may be further improved by micro-oxygenation with increase of some aroma attributes (plum, currant, spicy, and liquorice) and decrease of herbaceous aroma (Cejudo-Bastante et al. 2011), while aging on lees changes aroma balance by binding volatile compounds, such as lactones, terpenoids, ketones, aldehydes, and esters (Liberatore et al. 2010).

Membrane distillation is a relatively novel membrane process, which can be applied for the recovery of aroma compounds (Gryta 2005). Dense hydrophobic membranes with pores filled by gas phase are used in this process. The hydrophobic nature of the membrane prevents penetration of the wine into the pores. Therefore, only volatile components of the wine may be transported through the membrane. The concentration gradient of some particular volatile species in the gas phase at both ends of the membrane pores causes their transport across the membrane. The composition of the gas phase above the liquid surface is often expressed by the partial pressure, and thus the partial pressure difference can be used as a driving force of the membrane distillation process. The value of this driving force depends upon the temperature and composition in the layers adjacent to the membrane surface. When the driving force is obtained by partial pressure reduction on the permeate side by applying vacuum or blowing a sweep inert gas on this side, the membrane separation process is called pervaporation (Fig. 1). Usually the pressure of the permeant components is lower than their saturation pressure, and these components are therefore removed as vapor. Permeate should be collected

Wine Aroma Enhancement,

Fig. 1 Aroma recovery by pervaporation

in traps, which are normally cooled by using cold water or liquid nitrogen.

Wine Aroma Enhancement, Membrane Operations of

Johannes De Bruijn
Department of Agroindustry, Food Engineering Group, Universidad de Concepcion, Chillan, Chile

Wine aroma enhancement – The aroma profile of wine is made up by a subtle ratio between compounds of widely varying sensory properties.

During wine making, several components are lost due to their high volatility in aqueous solutions. These compounds are rather important for the sensorial quality of wines and might therefore be recovered and added back to the wines. Complete aroma recovery before dealcoholization and adding back to dealcoholized wine is another application (Catarino and Mendes 2011). Pervaporation, osmotic distillation or evaporative perstraction, reversed osmosis, and nanofiltration may constitute promising membrane processes for recovering aroma compounds from wines.

Pervaporation – This separation process is based on selective transport inside a dense hydrophobic membrane associated with the evaporation of the permeant. Aroma compounds permeate through the membrane due to the vacuum on the downstream side of the membrane. Once the aroma compounds leave the membrane as vapor, they will be condensed and collected under cryogenic temperature. Poly-octyl-methyl-siloxane/polyetherimide composite asymmetric membrane or poly-dimethyl-siloxane flat sheet or spiral wound membranes may be used for the aroma recovery from wine by pervaporation.

Osmotic distillation or evaporative perstraction – This process involves the use of a microporous hydrophobic membrane to separate two circulating aqueous solutions at different solute concentrations. The wine phase containing the volatile components circulates through a hollow fiber membrane contactor, while the stripping

Wine Aroma Enhancement, Membrane Operations of, Table 1 Solute rejection by RO and NF membranes (Labanda et al. 2009)

Compound	Osmonics – SE	Rejection (%)	
		Toray – UB70	Osmonics – DK
Diethyl succinate	99	96	97
2-Phenyl-ethanol	97	95	95
cis-3-Hexenol	80	77	85
Isovaleric acid	86	76	65

liquid, e.g., degassed water, flows along the downstream side of the membrane. When operating pressure is kept below the capillary penetration pressure of liquid into the pores, the membrane is not wetted by the circulating solutions, and air gaps are formed within the pores of the membrane. Process will be performed at room temperature, causing no thermal degradation of volatile compounds. Solubility of wine aroma compounds is higher in the wine phase than in pure water, so their transfer into the stripping phase is limited. On the other hand, ethanol is preferentially transferred across the membrane pores into the stripping phase due to the vapor pressure gradient between the feed and stripping phase (Diban et al. 2008).

Nanofiltration and reversed osmosis – Concentration of specific aroma compounds such as diethyl succinate (wine aging), 2-phenyl-ethanol (floral note), cis-3-hexenol (herbaceous note), and isovaleric acid (undesired note) of model white wine can be achieved by reversed osmosis and nanofiltration using flat sheet polymeric membranes in a batch retentate-recycling mode. High solute rejection values indicate enhanced aroma concentration in the retentate stream phase (Table 1) (Labanda et al. 2009).

Wine Clarification by Membrane Operations

Johannes De Bruijn

Department of Agroindustry, Food Engineering Group, Universidad de Concepcion, Chillan, Chile

Wine Clarification

Wine turbidity is caused by suspended material like yeast residues and macromolecular compounds with colloidal behavior. The clarification operation to remove this material is traditionally performed by diatomaceous earth filtration and membrane operations have been relatively restricted because of possible removal of polysaccharides and other macromolecules that may be of major relevance to wine quality.

Cross-Flow Microfiltration

This more recent operation uses a selective porous membrane that filters a wine in order to achieve its purification or clarification, resulting into a clear appearance and making the wine microbiologically stable. By creating a turbulent stream on the surface of the membrane, settling of filtered particles on the membrane will be prevented. Two

Wine Clarification by Membrane Operations, Fig. 1 Cross-flow ultrafiltration of white wine

main types of membranes are currently available: organic membranes made from polymeric material and inorganic membranes made from ceramics. Hollow fiber membrane systems are generally preferred. This membrane geometry is very compact, which means that a large filtration area per unit of volume will be available. Moreover, it does not require a large recirculation flow rate, giving less mixing and heating of the wine.

Process Integration

This relatively new concept involves the coupling of two or more unit operations that provide a more efficient separation than each operation alone. The integration of adsorption and cross-flow microfiltration may reduce unstable protein concentration in white wine, increasing at the same time the permeate flux of microfiltration due to less severe membrane fouling. After adsorption using a packed column of zirconium oxide pellets and cross-flow microfiltration using a ceramic membrane of zirconium oxide with a pore size of 0.2 μm , an increase of 15–20 % of the permeate flux has been observed. About 47 % of the total protein concentration and 15 % of the total polyphenol concentration have been lost during the adsorption stage. Only the percentage of total, volatile, and fixed acidity of wine decreased after using the hybrid process without changing the

other physicochemical wine properties (Salazar et al. 2007).

Cross-Flow Ultrafiltration

This membrane operation may be a good alternative for white wine clarification instead of cross-flow microfiltration in terms of productivity, wine quality, and tartaric stability (Fig. 1). Use of polymeric ultrafiltration membranes with a molecular weight cut-off of 100 kDa proved to have similar clarification performance for white wine as polymeric microfiltration membranes with 1.0 μm pore size. Polysaccharide removal was low with both microfiltration and ultrafiltration membranes. Wine polysaccharides may act as precipitation inhibitors of potassium hydrogen tartrate crystallization and their removal may decrease tartaric stability of wine (Gonçalves et al. 2001).

Wine Clarification by Microfiltration

Johannes De Bruijn

Department of Agroindustry, Food Engineering Group, Universidad de Concepcion, Chillan, Chile

Wine clarification – Crude wine is a complex medium with a turbid aspect. This latter is not well accepted by the consumer, and wine needs to be clarified removing particles such as microorganisms (yeast and bacteria), cell debris, colloidal aggregates (tannin, pectin, and mannoprotein), and potassium tartrate crystals by microfiltration. Thus, the key roles of clarification are to provide limpidity and microbiological stabilization of wines.

Microfiltration – Cross-flow microfiltration could be an alternative for traditional solid–liquid separation technologies such as centrifugation, filtration on sheets, diatomaceous earth filtration, and the use of exogenous additives during wine making. It offers several advantages such as no health and environmental problems because of the elimination of diatomaceous earth use, as well as the combination of clarification, stabilization, and sterile filtration in one single continuous unit operation without significantly modifying sensory quality of wines. The wine to be filtered flows parallel to the membrane surface and solutes and salts pass through the membrane by mean of a pressure drop. The shear exerted by the feed solution flowing parallel to the membrane surface may sweep deposited particles toward the retentate side, and so the deposited layer of particles and colloids remains relatively thin (Fig. 1).

The correct choice of operating conditions and membrane plays a key role to minimize membrane fouling. Microfiltration performance is governed by colloids and small particles, where these constituents result into a sharp initial flux decline related to both internal and external fouling. Therefore wine filtration should be done below critical flux above which an irreversible deposit appears at the membrane surface. Applied pressure should be smaller than the critical

Wine Clarification by Microfiltration, Fig. 1 Cross-flow microfiltration

pressure, where the particles brought to the membrane surface by the permeate flow are transported back into the bulk suspension by diffusion and flow out of the membrane. Transmembrane pressure is generally in the range between 1 and 3 bars. Moreover, cross-flow velocity affects mass transport of particles nearby membrane surface by increasing shear stress and shear induced diffusion. A cross-flow velocity of 2 m/s is usually applied, which insures sufficient shear stress and preserves wine quality. A major problem of increasing cross-flow velocity is the rise of wine temperature. Temperature should not exceed 25 °C in order to not modify sensorial characteristics of wine. Furthermore, organic membranes of cellulose acetate, polypropylene, polyethersulfone, and polyvinylidene difluoride and ceramic membranes of zirconium oxide, alumina, and titanium oxide with an average pore diameter of 0.2 µm for red wines and 0.1–0.22 µm for white wines show fair results in terms of permeate flux and wine quality (El Rayess et al. 2011).

X-Ray Diffraction (XRD)

Alberto Cassetta

Istituto di Cristallografia – CNR UOS di Trieste,
Italy

X-ray diffraction occurs when an electromagnetic wave of wavelength of the order of magnitude of 1 Å interacts with an ordered array of atoms like a molecular or ionic crystal. When the electromagnetic wave interacts with the electrons of an atom, a secondary wave (of the same wavelength) is scattered in all directions by the atom itself. The secondary waves produced by the three-dimensional regular array of atoms give rise to interference phenomena which can be destructive or constructive depending on the relative disposition of the atoms. Constructive interference results in diffracted rays scattered only along well-defined directions. The directions and the intensities of the diffracted rays depend on the crystal symmetry and on the atomic number and spatial distribution of the atoms inside the crystal and the set of diffracted rays, thus containing information about the three-dimensional atomic structure of the crystal.

Following Bragg's description of X-ray diffraction, we can assume a crystal as made of infinite planes containing atoms and whose orientations are dependent from the crystal unit

cell parameters. Each family of planes will then diffract according to Bragg's law (Warren 1990):

$$n\lambda = 2d\sin\theta$$

where n is the “order” of the plane, λ is the wavelength of the X-ray, d is the distance between the planes of the family, and θ is the angle between the wave and the plane. Furthermore, a complex but well-defined mathematical relation links the diffracted waves directions and intensities with the electron density inside the diffracting object (Warren 1990).

Therefore, due to their relationship with the spatial arrangements of the atoms inside a periodic structure, the acquisition of the diffracted rays from a material having an internal atomic periodicity (from 1D to 3D) may give important insights into the atomic structure of the material itself.

Experimentally, an X-ray diffraction experiment depends on the physical state of the matter: crystalline (single crystal or polycrystalline), an ordered surface (2D periodicity only), or even with an order in one dimension only like in fibers. In any case the experiments require three essential parts: an X-ray source which is in general monochromatic (conventional sources or synchrotron), a goniometer which is used to orient the sample according to the Bragg's law, and a detector which may be mono- or bidimensional and is used to collect the diffracted rays from the sample (Roe 2000).

X-ray diffraction is a well-established technique in membranes science (Bower 2002), mostly used for structural characterization but also for the analysis of physical processes occurring at membrane interfaces.

X-ray diffraction has been the main technique for the determination of crystalline polymers

structure. From the diffraction pattern of well-aligned polymer crystallites, it is possible to obtain the unit cell parameters, by inspecting the diffraction pattern geometry and intensities. A more quantitative study, normally carried out on polycrystalline samples (powder diffraction, Fig. 1), may lead to the structural determination

X-Ray Diffraction (XRD),

Fig. 1 (a) 2D powder diffraction pattern of a copolymer based on alternate benzothiadiazole and dioctylfluorene moieties and (b) its integrated pattern (Courtesy of Drs W. Porzio and L. Barba)

of the unit cell content, thus giving a molecular model of the crystalline polymer. Besides, polymer crystal diffraction patterns generally do not contain the full information needed for a complete crystal structure determination, and a modeling procedure is employed by exploiting crystal packing hypothesis based on polymer physics knowledge. The final accepted model is the one which best reproduces the experimental diffraction pattern.

X-ray diffraction is also used in polymer chemistry to estimate the crystallinity index, by evaluating the different contributions to the total diffracted intensity of the amorphous and crystalline components of the sample.

Finally, if one or more of the components of the membrane are in the crystalline state, the analysis of the membrane diffraction pattern may give important insights into the material modification upon membrane preparation.

X-Ray Synchrotron

Alberto Cassetta

Istituto di Cristallografia – CNR UOS di Trieste, Italy

Synchrotron radiation (SR) is produced when charged particles moving at relativistic speed are forced to change their trajectory by a magnetic field. Those particles, typically electrons, loose energy under the form of electromagnetic radiation, and due to their relativistic speed, the emitted radiation is confined in a narrow cone along the direction of the electron's motion (Fig. 1), with a continuous energy spectrum ranging from far infrared to X-ray regions.

In a synchrotron, bunches of electrons circulate in a closed orbit and the electrons are forced to change their directions by magnets, producing intense SR beams tangentially to the magnets themselves. The radiation thus produced is extremely intense and collimated in a narrow vertical angle and can deliver to the sample huge amounts of X-ray photons, several order of magnitude more than conventional laboratory sources (Duke 2008).

Nowadays, dedicated synchrotrons are built in order to produce extremely brilliant (intense and collimated) X-ray beams, whose properties depend on the synchrotron construction parameters. Apart from intensity and collimation, SR possesses other interesting properties: a continuous spectrum, a high degree of polarization, and a well-defined time structure. All of these properties can be properly tuned for specific X-ray experiments. Apart from bending magnets, which keep the electrons in a closed path, other magnetic devices called *insertion devices* (*wigglers* and *undulators*) are inserted in the straight sections of modern storage rings and can produce even more intense and collimated X-ray beams (Fig. 2).

SR is conveyed into a pipe, the beamline, where it is optically modified in terms of wavelength selection, focusing properties and final beam size. It is finally delivered to the sample, according to the kind of experiment (Margaritondo 2002).

Synchrotrons are generally built for specific SR wavelengths with specific machine characteristics. Lower-energy X-ray beams normally indicated as “soft X-rays” have energies roughly in the range 100–1,000 eV (≈ 10 –1 nm), whereas “hard X-rays” are in the range of 10–100 keV (≈ 0.1 –0.01 nm).

The X-rays produced by synchrotrons have very attractive characteristics for the materials science researcher, which can exploit not only the high photon flux of the SR but also the high collimation of the beam.

Highly brilliant X-ray beam with a size of few μm to few hundreds of nm has been produced and used for microdiffraction experiments. With such a small beam section, the scanning of a single polymeric fiber was possible pinpointing to

X-Ray Synchrotron, Fig. 1 Simplified representation of the angular distribution of emitted radiation from electrons moving at relativistic and nonrelativistic speed and traveling in a circular path

X-Ray Synchrotron, Fig. 2 Sketch of a modern SR-dedicated storage ring. (A) Emitted synchrotron radiation; (B) bending magnets; (C) insertion devices (wigglers,

undulators); (D) quadrupole magnets; (E) radio-frequency cavity; (F) injection magnet. Electron path is represented in magenta

domain inhomogeneities in both size and orientations (Riekel and Davies 2004). The same micro-beam approach was also applied to SAXS and WAXS techniques.

Highly intense and extremely collimated SR beams have also been largely used in SAXS experiments, to provide structural information on the nm size of polymeric and biological

membranes (like lipid bilayers). Soft matter, like biological membranes, is well known as low X-ray scattering material, and the intense SR beam is a unique tool for SAXS studies. Moreover, the strong collimation of the beam allows a resolution impossible to be reached with conventional sources. Wavelength tunability is another characteristic of SR largely exploited in SAXS, where time structure of SR has been used in time-resolved experiments (Chu and Hsueh 2001).

X-ray-based imaging techniques applied to hard and soft matter gained a great benefit from the use of intense and small X-ray beam as for tomographic methods. X-ray photoelectron spectroscopy methods also received a great impulse from the use of X-ray synchrotron radiation. Chemical analysis with photoelectron spectroscopy requires tunable and brilliant SR beams in order to chemically and electronically characterize surfaces like metal-based membranes.

X-Ray Synchrotron Microtomography

Alberto Cassetta

Istituto di Cristallografia – CNR UOS di Trieste, Italy

Tomography has its roots in radiology: an X-ray beam hits a sample and the transmitted beam is recorded by a detector. The ratio of the transmitted to incident intensities will depend on the line integral of the absorption coefficient μ of the materials (which increase with the atomic

number Z) along the beam path in the sample. The resulting image will thus be a 2D projection of the volumetric absorption coefficient of the sample itself. In tomography many 2D images (radiography) are acquired at different sample orientations, for a total angle of 180° . The images are then combined together through a mathematical algorithm in order to give a 3D reconstruction, in the form of sliced 2D maps, of the different absorption coefficient inside the sample, clearly related to its chemical composition.

Synchrotron X-ray sources are unique in their properties for tomographic analysis. The intense synchrotron X-ray beam allows the resolution of subtle variations in absorptivity due to an extremely good signal-to-noise ratio. Moreover, a synchrotron X-ray beam can be considered essentially parallel which simplifies the mathematical treatment of image reconstruction, which actually assumes a parallel beam. Synchrotron radiation can be tuned for the optimization of the contrast between the chemically different constituents of the sample and for avoiding aberrations originating from the use of polychromatic beams. Finally, exploiting the partial coherence of a synchrotron X-ray beam, “phase contrast” microtomographic techniques, based on the different refractive index of different materials, can be used in order to gain further resolution in image reconstruction. On the whole, synchrotron radiation-computed microtomography (SR- μ CT) allows a spatial resolution on μm and even sub- μm order which results in a digital reconstruction of the scanned volume apt for qualitative and quantitative analysis (Bonse and Busch 1996).

The setup of a typical SR- μ CT experiment requires an X-ray source in the range of the hard X-ray region (from 8 keV upward) having a linear size of few tens of μm or less. The X-ray beam is monochromatized and reduced to the appropriate size by a slits system. The sample, generally of few mm in linear dimensions, is mounted on a holder and fitted onto a goniometer for proper orientations. Images are typically collected from a 2D detector which is often a scintillator optically coupled with a high-resolution CCD camera with a small pixel size. Depending on the beamline setup, focusing elements may also be present

X-Ray Synchrotron Microtomography, Fig. 1 Schematic representation of a synchrotron radiation microtomography experiment

before and after the sample in order to gain further resolution. Given the high brightness of the synchrotron beam, hundreds to thousands of images can be collected in a relatively small amount of time. Image processing is computed offline by using appropriate algorithms such as the “filtered back projection” or “direct Fourier inversion” methods which are found in dedicated image reconstruction software packages (Fig. 1).

SR- μ CT is a valuable tool in membrane structure analysis as provided by a nondestructive method for the investigation, at the micrometric size, of both the bulk and the interface structure of the membrane. Tomographic methods do not require specific sample preparation, finally giving a high-resolution 3D representation of the “native” sample under study.

SR- μ CT has been widely used in order to gain insights into the water distribution in polymer electrolyte membrane fuel cells (PEMFC) in response to various operation conditions. By using SR- μ CT the correlation between the wetness of the polymer electrolyte membrane, its structure, and its proton conductivity has been established (Manke et al. 2011).

A typical application of SR- μ CT to membrane science is the structural investigation of the membrane porosity. Exploiting the different absorption coefficient between the polymer and water is possible to investigate the porosity of the membrane in a quantitative way. Different porosity across the membrane is easily spotted from 3D sample reconstruction, and an estimation of the shape and dimensions of the pores is also possible due to the high resolution attainable with SR- μ CT (Remigny et al. 2007).

Young's Model

Wolfgang M. Sigmund and Shu-Hau Hsu
Department of Materials Science and
Engineering, University of Florida, Gainesville,
FL, USA

Department of Energy Engineering, Hanyang
University, Seoul, Republic of Korea

Young's model is commonly used to illustrate the wettability of solid surfaces. To better understand this behavior, surface tension or interfacial tension has to be introduced. Surface tension is a tensor that acts perpendicularly to a line on the surface and is caused by the imbalance of attractive forces at the surface where surface atoms, molecules, or ions are surrounded by a reduced number of similar species than those in the interior or have larger distances to their nearest neighbors. This causes liquid molecules at the surface to be in an

energetically unfavorable state, and therefore the surface generates a force to minimize its free surface area. When a waterdrop rests on a perfectly smooth solid surface, it forms a spherical cap whose shape is determined by the balance of the interfacial tensions (γ) between three different phases (liquid/air/solid) (Fig. 1). The contact angle (θ_c) between the water sphere and solid can be addressed as

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos \theta_C \quad (1)$$

This was first described in Thomas Young's essay in 1805. If the value of the static contact angle is $0^\circ \leq \theta_c \leq 90^\circ$, the liquid tends to spread on the surface. It is usually referred to as hydrophilic or oleophilic surface in terms of aqueous or oily liquids, respectively. If the value of the contact angle is $90^\circ < \theta_c \leq 180^\circ$, the wet area tends to shrink. It is then referred to as hydrophobic or oleophobic surface in terms of aqueous or oily

Young's Model, Fig. 1 A drop of water on solid surface. The contact angle (θ_c) is the balance of three different interfacial tensions (Hsu 2010)

liquid, respectively. Surfaces with the water contact angle between 150° and 180° are usually called superhydrophobic.

Zeolite A Type

Anne Julbe and Martin Drobek
Institut Européen des Membranes, Université de
Montpellier, Montpellier, France

Zeolite A, also known as LTA (Linde Type A), belongs to the family of aluminosilicate molecular sieves. It is characterized by the formula $[(\text{Na}^+_{12}(\text{H}_2\text{O})_{27})_8[\text{Al}_{12}\text{Si}_{12}\text{O}_{48}]_8$ which corresponds to its most common hydrated sodium form (International Zeolite Association -IZA). Sodium ions in zeolite A can be exchanged with other cations such as lithium (Li-LTA), potassium (K-LTA), or calcium (Ca-LTA) (Townsend and Coker 2001). The principal building units of zeolite A are sodalite cages which are connected by four-membered rings forming a three-dimensional (3D) network (Fig. 1). These cages consist of central cavities of 11.4 Å in diameter (supercage) interconnected by eight-ring openings with a 4.1 Å aperture, thus forming a remarkably open zeolite framework with a high void volume fraction of 47 % (McCusker and Baerlocher 2001). The structure is cubic, represented by $a_0 = 11.919$ Å and the space group Pm-3m. When Na^+ is exchanged with the larger K^+ , the pore opening is reduced to approximately 3 Å

(K-LTA or 3A zeolite). In the case that Ca^{2+} replaces 2Na^+ , the pore opening increases to approximately 5 Å (Ca-LTA or 5A zeolite). Due to aperture size, the Na-LTA zeolite is also called 4A zeolite.

Zeolite A does not occur in nature and must be prepared synthetically by hydrothermal crystallization of reactive alkali metal aluminosilicate gels at low temperatures (~ 100 °C) and pressures (autogenous) under alkaline condition (pH typically higher than 12) (Yu 2007). Since its discovery at the Union Carbide Corporation Laboratories (Linde Division-Union Carbide) in the 1950s (Reed and Breck 1956), zeolite A has been largely investigated and applied at large scale for a variety of separations and purifications (Flanigen 1980). Due to its high water adsorption capacity, LTA zeolite has been first used as a desiccant for technical gases and liquids. In 1959 Union Carbide marketed the IsoSiv process for normal isoparaffin separation, representing the first major bulk separation process using true molecular sieving selectivity. The supercage structure revealed also useful for spacio-specific catalysis, such as paraffin cracking. Owing to its active ion exchange properties, zeolite A is also widely used in detergents since the mid 1970s, particularly as a replacement for the environmentally harmful phosphates for water softening. In

Zeolite A Type, Fig. 1 The type A zeolite structure – view along [100] direction (International Zeolite Association (IZA))

1999, Mitsui Engineering and Shipping Co. Ltd. manufactured the first LTA membranes to the market for the dehydration of ethanol, which was a milestone in the commercialization of zeolite A as a continuous selective barrier (Morigami et al. 2001).

Zeolite membrane: Synthesis

Zeolite membranes are selective barriers, which can be supported or not, and prepared with well-defined aluminosilicate crystalline structures having a uniform and well-defined porous framework. Zeolites are attractive molecular sieve materials which have been used for a long time as adsorbents, catalysts, and softeners in detergents (ion-exchange properties). Since the early 1990s, zeolite membranes attracted considerable attention in many research and industrial groups, exploring their potential for the continuous separation of liquids, gas, and vapors, for chemical synthesis, pollution abatement, catalytic reactors, micro-reactors, sensors, electrodes, and optoelectronic devices (Caro and Noack 2008; Julbe 2007). Among the 229 currently known zeolitic framework type codes assigned to date by the [International Zeolite Structure Commission \(www.iza-online.org\)](http://www.iza-online.org), less than 10 % have been prepared in a form of membrane. The most studied membrane structures are LTA, MFI, CHA, SOD, DDR, FER, MEL, MFI, ERI-OFF, MOR, FAU, and BEA types (www.iza-online.org).

Several strategies have been developed for preparing zeolite membranes (supported or self-supported), such as embedding methods, in situ hydrothermal synthesis or seeding, and secondary growth (Julbe 2007). Embedding is typically used for the preparation of composite membranes (often referred as mixed matrix membranes) containing zeolite particles dispersed in a bulk matrix, generally a polymer. Zeolite membranes are usually supported, anchored, or grown on/in a porous supports with adapted mechanical, thermal, and chemical resistance (typically ceramics or metals). The seeding and secondary growth

Zeolite Membrane,

Fig. 1 MFI zeolite membrane obtained by secondary growth on a porous α - Al_2O_3 support (Motuzas et al. 2006)

strategy is now considered as the most attractive method for preparing a variety of zeolite (e.g., LTA, MFI, SOD, FAU, CHA, DDR) and zeolite-type (e.g., MCM, MOF) membranes. It confers improved flexibility for controlling crystal growth and film microstructure with high reproducibility and scalability compared to direct in situ hydrothermal synthesis (Motuzas et al. 2006). Supported MFI membrane prepared by secondary growth from a layer of silicalite-1 seeds is shown in Fig. 1. Concerning zeolite membrane industrialization, LTA membranes were the first to be prepared at large scale by Mitsui Engineering and Shipbuilding Co. for the dehydration of ethanol (Kodo et al. 1997). Other companies or research centers, including IKTS/Inocermic in Germany, ECN and Pervatech in the Netherlands, Kühni in Switzerland, and Hitachi Zosen in Japan as well as Mitsubishi Chemical Corporation, also developed zeolite-based pervaporation or vapor permeation dehydration systems (Pina et al. 2011). Recently, upscaling of SAPO-34 (Li et al. 2010) and all-silica DDR membranes (Makiko and Kenji 2012) has been considered, respectively, by Shell and NGK Insulators Ltd. for CO_2/CH_4 separation. Other types of zeolite membranes, including MFI, FAU (NaX, NaY), MOR, and T-type membranes, are considered for various applications of high industrial impact. Bussan Nanotech Research Institute Inc., namely, reported on mass production of tubular NaY

zeolite membranes for ethanol dehydration (Sato et al. 2008).

Zeolite Membrane: Synthesis

► Zeolite Membrane

Zeolite T Type

Anne Julbe and Martin Drobek
Institut Européen des Membranes, Université de Montpellier, Montpellier, France

Zeolite T (Linde type T) is a crystalline aluminosilicate with hexagonal symmetry. Its typical formula is $0.3\text{Na}_2\text{O} \cdot 0.7\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6.9\text{SiO}_2 \cdot 7.2\text{H}_2\text{O}$. It corresponds to a disordered intergrowth of erionite and offretite structures in which the more open offretite (12-ring main channels parallel to the c-axis and 8-ring sub-channels normal to the c-axis with pore sizes of 0.67×0.68 nm and 0.36×0.49 nm, respectively) (Fig. 1) is interspersed at intervals with the tighter erionite units (8-ring channels parallel to the c-axis with pore size of 0.36×0.51 nm) (Spivey et al. 1992). The framework structures of offretite and erionite are closely related, and the synthesized zeolite T is mainly composed of the offretite phase with only small amounts of erionite

sheets. Due to the specific position of single erionite unit cells at the end of the large pore of offretite, erionite controls the diffusion path by forcing the molecules to pass through the small 8-rings erionite rings. Pure erionite and offretite phases can be obtained only in the presence of an organic template, whereas intergrowth-type zeolite T can be synthesized without any template. Zeolite T, with intermediate Si/Al ratio of 3–4, is acid resistant and thermally stable while remaining hydrophilic. Its high acid resistance often overpasses other more common zeolites such as A, X, and Y. Zeolite T can be used for the selective adsorption or drying of acid gases and liquids at high temperatures. Both erionite and intergrowth offretite/erionite zeolite types have been reported as very attractive materials for catalysis or selective barriers applicable in conversion of methanol to $\text{C}_2\text{--C}_5$ olefins, selective catalytic dewaxing, and molecular sieving of n-butane (Yang and Evmiridis 1996). Zeolite T membranes have enormous potential for industrial dehydration processes, e.g., separating water from organic liquids in acidic environment, such as esterification hybrid process (Zhou et al. 2009). Due to their molecular sieving properties, zeolite T membranes have been also considered for gas separation applications, namely for separating CO_2/N_2 and CO_2/CH_4 mixtures up to 473K (Cui et al. 2004, see also Zhang et al. 2013).

Zeolite X Type

Anne Julbe and Martin Drobek
Institut Européen des Membranes, Université de Montpellier, Montpellier, France

Zeolite X, together with zeolite Y, belongs to the family of aluminosilicate molecular sieves with a faujasite-type structure (FAU). It is characterized by the formula $[(Ca, Mg, Na_2)_{29} (H_2O)_{240} [Al_{58}Si_{134}O_{384}] - FAU$ (International zeolite association (IZA)). Faujasite is a rare zeolite, although its synthetic counterparts Linde X and Linde Y are largely used as sorbents and catalysts. Zeolite X differs from zeolite Y by its Si/Al atomic ratio which is typically in the range from 1 to 1.5 for the X and higher for the Y-type zeolite. High Si/Al ratio is desirable towards thermal stability, a property that is less favorable to zeolite X. The 24 tetrahedra cuboctahedral units (sodalite cages) in the FAU framework type are arranged in the same way as the carbon atoms in diamond. They are connected via hexagonal prisms (double six rings) forming a three-dimensional porous channel

structure along [110], characterized by 12 oxygen ring window openings with the aperture of 8 Å and supercages of approximately 12 Å (McCusker and Baerlocher 2001). The FAU-type zeolite supercage viewed along [111] is shown in Fig. 1 (International zeolite association (IZA)).

The combination of large void volumes and large pore openings in a three-dimensional channel system makes FAU molecular sieve ideal for many catalytic applications. This zeolite is also attractive for its ion exchange and adsorptive properties.

The combination of Si⁴⁺ and Al³⁺ results in a deficiency of positive charge which is balanced by exchangeable cations. Due to its very low Si/Al ratio, the zeolite X framework provides a large number of cation exchange sites balancing the framework aluminum, thus leading to high cation contents and exchange capacities. Zeolite X is generally synthesized by hydrothermal crystallization of reactive alkali metal aluminosilicate gels or clear solutions at low temperature (70–300 °C, usually 100 °C) and pressure (autogenous) under alkaline conditions. Starting typically from sodium aluminate and sodium silicate, zeolite

Zeolite X Type, Fig. 1 The FAU type zeolite supercage – view along [111] direction (www.iza-online.org)

X is obtained in its Na^+ form. Zeolite NaX is a metastable phase, meaning that other types of zeolites such as P, A, or sodalite may form if the recipe is not followed carefully (Balkus and Ly 1991). For specific catalytic applications, the incorporation of various metal cations into the structure can be carried out by impregnation or ion exchange. This results in the modification of the number and nature of acid sites influencing the diffusion of reactants and products. A large variety of cationic species has been introduced into FAU frameworks. X-type zeolite has a wide range of industrial applications for gas or vapor adsorption, separation, and as catalyst. Examples of applications in chemical reactions include isomerization of 1-butene, alkylation of toluene with ethylene or methanol, and cycloaddition of carbon dioxide to ethylene oxide (Ribeiro et al. 1984). X-type zeolites can be used to adsorb an unwanted compound during decomposition reactions such as removal of alkyl hydroperoxides from ethers and olefins during hydrobromination of alkenes (Wortel and van Bekkum 1980). Alcohol dehydration by pervaporation is a potential application for X-type membranes (Zhou et al. 2012). However, in many large-scale industrial applications, its chemical analogue with Si/Al ratio higher than 1.5 (zeolite Y) has superseded zeolite X because of its higher chemical and thermal stability.

Zeolite Y Type

Anne Julbe and Martin Drobek

Institut Européen des Membranes, Université de Montpellier, Montpellier, France

Zeolite Y, together with zeolite X, belongs to the family of aluminosilicate molecular sieves with a faujasite-type structure (FAU), which is characterized by the basic formula $[(\text{Ca}, \text{Mg}, \text{Na}_2)_{29}(\text{H}_2\text{O})_{240}][\text{Al}_{58}\text{Si}_{134}\text{O}_{384}]$ –FAU (Baerlocher 2007). Faujasite is a rare zeolite, although its synthetic counterparts Linde X and Linde Y are largely used as sorbents and catalysts. Zeolite Y has a higher Si/Al atomic ratio than zeolite X (typically in the range 1–1.5). Therefore, the higher content of silica confers zeolite Y with higher thermal stability. The 24-tetrahedracuboctahedral units (sodalite cages) in the FAU framework type are arranged in the same way as the carbon atoms in diamond. They are connected via hexagonal prisms (double 6-rings) forming a 3-dimensional porous channel structure along [110], characterized by 12-oxygen ring window openings with the aperture of 8 Å and supercages of approximately 12 Å (McCusker and Baerlocher 2001). The FAU-type zeolite supercage viewed along [111] is shown in Fig. 1

The combination of large void volume and large pore openings in a 3-dimensional channel system makes this thermally stable FAU molecular sieve ideal for many catalytic applications. This zeolite is also considered for its ion-exchange and adsorptive properties. Zeolite Y is generally synthesized by hydrothermal crystallisation of reactive alkali metal aluminosilicate gels or clear solutions at low temperature (70–300 °C, usually 100 °C) and pressure (autogenous) under alkaline conditions. Starting typically from sodium aluminate and sodium silicate, the Y zeolite is obtained in its Na^+ form (Blatter and Schumacher 1991) and a replacement of the Na^+ cations by protons (leading to the H-zeolite form) is required for applications in acid catalysis. Due to the poor stability of the FAU structure in acidic media, this conversion is

Zeolite Y Type, Fig. 1 The FAU type zeolite supercage – view along [111] direction (www.iza-online.org)

done indirectly via an ammonium exchange resulting in $\text{NH}_4^+ \text{Y}$, where the cation is decomposed into ammonia and protons, thus yielding a highly crystalline H-FAU structure. Dealumination of the Y zeolite framework results in the formation of ultra-stable Y zeolite (USY) with high (hydro)thermal stability. USY prepared by thermal, hydrothermal, or chemical dealumination of zeolite Y is one of the most widely employed zeolite material in the petrochemical industry. Zeolite Y is essentially used as a Fluid Cracking Catalyst (FCC) of heavy petroleum distillates, for increasing the yield of gasoline and Diesel fuel from crude oil (Kung et al. 2000). It is also used to increase the aromatic content of refinery products in hydrocracking units, when it is associated with platinum or palladium species, deposited by either impregnation or ion exchange (Ribeiro 1984). A large variety of other applications have been reported for the Y zeolite, including the dealcoholization of beer, the removal of toxic preservatives in the pharmaceutical preparation of insulin, the slow-release of drugs, or the encapsulation of specific ions for electrocatalytic applications (Pavelic and Hadzija 2003), also in addition to simple gas phase or liquid phase separations and treatments, including membranes (Morooka et al. 1998). Bussan

Nanotech Research Institute Inc., namely, reported on mass-production of tubular NaY zeolite membranes for ethanol dehydration (Sato et al. 2008).

Zeolite-Embedded Membrane

Anne Julbe and Martin Drobek
Institut Européen des Membranes, Université de Montpellier, Montpellier, France

Zeolite-embedded membranes belong to the family of composite selective barriers (also referred as mixed matrix membranes (MMMs)), which are

Zeolite-Embedded Membrane, Fig. 1 MMM with MFI zeolite particles (22 wt%) embedded in a PVDF polymer matrix (Drobek et al. 2015)

typically obtained by dispersing zeolite crystals in a bulk matrix, usually a polymer film (Bastani et al. 2013). Zeolite-filled MMMs have been intensively studied from the early 1970s as a strategy to overcome the permeability/selectivity trade-off of conventional polymeric membranes. The basic idea was to obtain a synergic effect by combining the high selectivity and permeability of zeolites with the attractive mechanical properties and economical processability of polymers. These membranes were intensively considered for difficult gas separations or pervaporation but also as interface contactors and in fuel cell applications (Jeong et al. 2010; Zornoza et al. 2011; Tricoli and Nannetti 2003). The key point of membrane efficiency bears on the selection of a relevant zeolite/polymer coupling, thus providing a good quality interfacial contact between the inorganic filler and the matrix (nonselective diffusion pathways). Several zeolite surface modification strategies, such as silanation, annealing, or Grignard treatments, have been considered to improve and optimize interfaces. Nanosize zeolite particles embedded in MMMs generally outperform MMMs prepared with micron size particles, when optimized loading and dispersion are used. Preparation of zeolite-embedded membranes (Fig. 1) is adapted from classical methods used for polymeric membranes, although membrane

processing steps and solvents that can “clog” the zeolites should be avoided. Early attempts at designing MMMs focused on gas separation using rubbery polymers such as polydimethylsiloxane (PDMS). Nowadays, glassy polymers such as polyimide (PI), polyethersulfone (PES), or copolymers are preferably used together with semicrystalline polyvinylidene fluoride (PVDF). The latter possesses excellent mechanical properties, thermal stability, and high chain movements, enabling preparation of membranes with high inorganic filler content. Typical zeolite fillers in MMMs are silicalite-1, ZSM-5, L, 3A, 4A, 5A, 13X, KY, H-SSZ-13 β -type, or SAPO-34 (Julbe 2007). Zeolite-type materials (e.g., MCM-41, MCM-48, SBA-15, ZIF) have been also considered, and highly attractive results were also obtained with the MOF (metal-organic frameworks) fillers which provide better interfacial contact with polymers (Bastani et al. 2013).

Zeolitic Imidazolate Framework-8

► ZIF-8 Membrane

Zeta Potential

Paul Melvyn Williams
College of Engineering, Swansea University,
Swansea, UK

Zeta potential: When two phases are placed in contact, there develops in general a difference in potential between them (Hunter 1981). The term zeta potential is an abbreviation for the electrokinetic potential in colloidal systems. In the colloidal chemistry literature, it is usually represented using the Greek letter zeta (ζ). The zeta potential is commonly associated with particulate systems but can also be measured for surfaces such as membranes. The zeta potential does not occur exactly at the interface, but is in fact the electric potential in the interfacial double layer at the location of the slipping plane (or outer Helmholtz plane) (Hunter 1981) versus a point in the bulk fluid away from the interface (see Fig. 1).

The zeta potential is used in DLVO theory (Hunter 1989) to describe the magnitude of the electrostatic forces (usually repulsive for liked

charged particles/surfaces) and give the potential stability of a colloidal system. For colloidal systems, a high zeta potential will confer stability, i.e., the solution or dispersion will resist aggregation/flocculation. When the zeta potential is low, attraction exceeds repulsion and the dispersion will flocculate. A value of 25 mV (positive or negative) is usually taken as the arbitrary value that separates low charged surfaces from highly charged surfaces. Colloids with a high magnitude of the zeta potential (positive or negative) are said to be electrically stabilized.

The zeta potential, however, is not measurable directly but can be calculated using theoretical models and experimentally determined values such as the electrophoretic mobility or the streaming potential. Electroacoustic phenomena may also be used for the calculation of zeta potential. The most known and widely used theory for calculating zeta potential from experimental data is that developed by Smoluchowski (1903). This theory was originally developed for electrophoresis; however, an extension to electroacoustics is now also available (Dukhin and Goetz 2002). Smoluchowski's theory is powerful because it is valid for dispersed particles of any shape and any concentration. Smoluchowski's theory does have limitations in that it is only valid for thin double layers and surface conductivity is neglected. More modern, rigorous electrokinetic theories that are valid for any zeta potential have been developed and are available in the literature (Dukhin and Semnikhin 1970; O'Brien and White 1978).

Zeta Potential Measurement

Rosalinda Mazzei

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Zeta potential measurement of a solution is calculated indirectly by determining the electrophoretic mobility of particle immersed in a liquid under an electrical field. The electrophoretic velocity can be determined in different ways (Merkus 2014):

- Directly under microscope.
- Measuring the Doppler shift of the frequency of scattered light (based on laser Doppler electrophoresis (LDE)) or the phase shift (based on phase analysis light scattering (PALS)), by light scattering systems.
- Measuring the colloid vibration potential (CVP) or current (CVC) or the electrokinetic sonic amplitude (ESA), by electroacoustic instruments.

Once the particle velocity was determined, knowing the electrical field applied and taking into account the viscosity and the dielectric constant of the sample, it is possible to determine the zeta potential applying Henry Eq. 1:

$$U_e = \frac{2\varepsilon z f(Ka)}{3\eta} \quad (1)$$

where z is the zeta potential, U_e is the electrophoretic mobility, ε is the dielectric constant, η is viscosity, and $f(Ka)$ is the Henry function. Henry function is related to the ratio of the particle radius and the thickness of the double layer. For $f(Ka)$ determination, two values are generally used (1.5 and 1.0).

The value of 1.5 is generally used for systems that fit the Smoluchowski model (particles larger than 0.2 μm with) and when the analysis was carried out in aqueous media and moderate electrolyte concentration (electrolyte concentration more than 10^{-3} molar). The value of 1 is generally used for small particles in low dielectric constant and also for sample in nonaqueous media.

Particles with zeta potential between -10 and $+10$ mV are considered neutral; greater than $+30$ mV are strongly cationic while less than -30 mV strongly anionic.

ZIF-8 Membrane Properties

Zeolitic imidazolate framework-8 (ZIF-8) membrane is a separation membrane which is

ZIF-8 Membrane,

Fig. 1 Structure of the zeolitic imidazolate framework-8 (H atoms are omitted for clarity)

fabricated using ZIF-8. ZIF-8 is classified as part of metal-organic frameworks (MOFs), which is connected with the coordination bonds between metal ions and organic ligands. ZIF-8 is composed of zinc atoms and 2-methylimidazole as a ligand that forms a sodalite topology having large cavities with a diameter of 1.16 nm, which are connected through a small pore aperture of 0.34 nm diameter (Fig. 1, Park et al. 2006).

The adsorption and diffusion characteristics of ZIF-8 have been investigated. It is reported that the ratio of the diffusion rate coefficients for propylene and propane is about 100–125, whereas the equilibrium adsorption capacities are almost identical (Li et al. 2009; Zhang et al. 2012b). Thus, it is concluded that the effective aperture size of ZIF-8 pore opening is between 0.40 and 0.42 nm, which are the van der Waals diameters of propylene and propane, respectively. The effective aperture size of ZIF-8 pore opening is larger than that obtained from crystallographic data (0.34 nm) due to the flexibility of the ZIF-8 pore structure. Therefore, ZIF-8 is recognized as a material for the separation of propylene/propane by molecular sieving.

Several methods have been reported for the preparation of the ZIF-8-based membranes. One

of the preparation methods for the ZIF-8 membrane is the mixed matrix membranes (MMMs), which combine the ZIF-8 particles with the polymer matrix. Preparation and the permeation properties are reported for several applications such as CO₂/N₂ separation (Lively et al. 2012), water/alcohol separation (Shi et al. 2012), and propylene/propane separation (Askari and Chung 2013; Zhang et al. 2012a).

ZIF-8 membranes with pure ZIF-8 selective layers are prepared from direct growth method, secondary growth method, and counter-diffusion method. In the direct growth method, ZIF-8 membranes are directly formed under the solvothermal conditions (Bux et al. 2009; McCarthy et al. 2010; Shah et al. 2013; Xu et al. 2011). Secondary growth method starts with the preparation of the seed layer followed by the growth of the ZIF-8 layer under solvothermal conditions (Bux et al. 2011; Ge et al. 2012; Kwon and Jeong 2013a; Li et al. 2013; Liu et al. 2014; Pan et al. 2012; Tao et al. 2013; Venna and Carreon 2010). Pan et al. reported the effective separation of propylene/propane with ZIF-8 membranes with selectivity up to 50 for an equimolar mixture of propylene/propane (Pan et al. 2012). Successively, Liu et al. also reported ZIF-8 membranes

with excellent propylene/propane separation performance (Liu et al. 2014). From the other method, counter-diffusion method, ZIF-8 layer is formed from the interface of the zinc salt and the 2-methylimidazole solutions, which is advantageous for decreasing the defect in the ZIF-8 layer. Kwon et al. reported the preparation and the permeation properties of ZIF-8 membranes with the selectivity up to 55 for an equimolar mixture of propylene/propane (Kwon and Jeong 2013a, b). Hara et al. reported the preparation of ZIF-8 membranes with the ideal separation factor up to 59, and the contribution of the diffusive separation of propylene/propane was determined from the single-component gas permeation properties (Hara et al. 2014).

ZIF-8 membrane has a high potentiality for various applications especially for the propylene/propane separation owing to its characteristic pore structure. Various researches are in progress for the preparation of the ZIF-8 membranes with both high permeance and high selectivity and also for the characterization of the membrane permeation properties.

Zinc Recovery by Supported Liquid Membrane

Carlos Moreno

Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, University of Cádiz, Puerto Real, Spain

Zinc is an essential element for life, being indispensable for humans, animals, and plants. It is also extensively used by humankind in many industrial applications (electrical or automotive industries, surface treatments, etc.), both directly and as oxides, sulfides, or in alloys such as brass.

Recovery of zinc by supported liquid membranes has been done at a laboratory scale. It may be carried out by using organic extractants commercially available, mostly phosphoric acid derivatives such as bis(2,4,4-trimethylpentyl) monothiophosphinic acid Fig. 1, bis(2-ethylhexyl) hydrogen phosphate, or bis(2,4,4-trimethylpentyl) phosphinic acid.

Zirconium-Phosphate (ZrP)-Filled Nafion Membrane

Monica Pica

University of Perugia, Department of Pharmaceutical Sciences, Perugia, Italy

Zirconium phosphate (ZrP)-filled Nafion membranes are a class of organo-inorgano composite membranes consisting of nanoparticles of an inorganic filler (ZrP) dispersed within a polymer matrix based on a perfluorosulfonic acid ionomer (Nafion).

Nafion is a sulfonated tetrafluoroethylene-based polymer, with perfluorovinyl ether side chains, terminated with sulfonic superacid groups (Fig. 1) (Mauritz and Moore 2004). According to the many different structural models, the morphology of Nafion membranes consists of hydrophilic channels, made up by the clustering of the sulfonic acid functional groups which are responsible for the proton transport; these channels are delimited by the hydrophobic perfluorinated polymer backbone, which assures thermal, chemical, and mechanical stability, especially at temperatures <80 °C.

Zirconium phosphate represents the earliest example of metal(IV) phosphate and phosphonate-layered compounds. The structure of the α -type ZrP is built up by the packing of layers made of planes of zirconium atoms bonded, on both plane sides, to monohydrogen phosphate groups (Fig. 2) (Clearfield and Costantino 1996). ZrP has been extensively studied as filler of polymers, especially ionomers (Alberti and Casciola 2003; Neburchilov et al. 2007) due to its thermal and chemical stability, to its proton conduction

Zirconium-Phosphate (ZrP)-Filled Nafion Membrane,

Fig. 1 Chemical structure of Nafion

Zirconium-Phosphate (ZrP)-Filled Nafion Membrane, Fig. 2 Schematic representation of ZrP-layered structure

properties, and to its ability to intercalate, within the layers, organic molecules and macromolecules, such as polymer chains, which could promote the layer separation (exfoliation) and their dispersion within the polymer matrix.

Three main synthetic procedures are known to prepare Nafion-ZrP membranes (Alberti et al. 2007):

- i. Dispersion of preformed filler particles in the polymer dispersion. According to this procedure, colloidal dispersions or gels of highly exfoliated ZrP particles are mixed with a Nafion dispersion in the same solvent. The membrane is then obtained by solution casting, followed by solvent evaporation.
- ii. In situ ZrP precipitation: this method is based on the use of preformed Nafion membranes and on the exchange of the membrane protons with zirconium cationic species, followed by treatment with phosphoric acid solutions.

- iii. "Precursor solution" method: a ZrP precursor solution in polar aprotic solvents is added to a Nafion dispersion in the same solvent: the precipitation of the ZrP particles occurs during the solvent evaporation from the cast mixture.

The properties of the composite membranes depend on the filler morphology and loading. It was found that the presence of the ZrP particles in Nafion membranes:

- Decreases the degree of crystallinity of the polymer (Bauer and Porada 2004; Alberti et al. 2007; Casciola et al. 2008)
- Increases the mechanical strength of the membranes (Alberti et al. 2007; Casciola et al. 2008)
- Decreases the proton conductivity with respect to the neat polymer (Alberti et al. 2007; Casciola et al. 2008)
- Improves the fuel cell performances at temperatures $>80^{\circ}\text{C}$ (Yang et al. 2004)
- Decreases the methanol permeability with respect to the neat polymer (Bauer and Porada 2004), especially when ZrP particles with high aspect ratio are employed as filler (Casciola et al. 2009)

ZSM-5 Zeolite Membrane

Anne Julbe and Martin Drobek
Institut Européen des Membranes, Université de Montpellier, Montpellier, France

ZSM-5 (Zeolite Socony Mobil-5, patented by Mobil oil company in 1975) is a high silica zeolite with a MFI framework structure (Mobil Five) characterized by the formula $[(\text{Na}_x(\text{H}_2\text{O}))_{16}[\text{Al}_x\text{Si}_{96-x}\text{O}_{192}]]$, where $x < 27$ (International Zeolite Association-IZA). It is composed of pentasil units which are linked to form pentasil chains connected via oxygen bridges to form corrugated sheets with 10-ring holes (Fig. 1). Oxygen bridges between these sheets result in a 3-dimensional system with straight 10-ring channels parallel to the corrugations (along y) and sinusoidal 10-ring channels perpendicular to the

ZSM-5 Zeolite Membrane, Fig. 1 The MFI type structure – view along [010] direction (International Zeolite Association-IZA)

sheets (along x). The MFI 3D framework, consisting of straight and zigzag channels, is a rather complex zeolite framework type. The structure is orthorhombic (space group Pnma) at high temperatures, but a phase transition to the monoclinic space group occurs on cooling below the transition temperature, i.e., between 300 and 350 K. Because the pore openings are 10-rings (straight channels have circular openings of 0.54–0.56 nm and sinusoidal channels have elliptical openings of 0.51–0.55 nm), the shape selectivity for sorption and catalysis resulted in many applications of this zeolite in refinery and petrochemical industry, including for hydrocarbon isomerization and alkylation of hydrocarbons (McCusker and Baerlocher 2001). ZSM-5 does not occur in natural rocks and must be prepared synthetically in basic media at high pressures (autogenous) and temperatures (typically 120–200 °C) from alumina and silica sources and eventually in the presence of structure directing agents such as tetrapropylammonium-based compounds. Seeds with the MFI structure can also be used to fasten the synthesis kinetics and generate uniform supported layers/membranes. The type of the raw materials and the presence/absence of template are of the utmost importance on the crystal morphology and the distribution of aluminum atoms in the framework, leading to the formation of zeolite catalyst with acidic properties which could be effectively

controlled during the synthesis. The acidity is proportional to the Al content and a number of positive charges (e.g., Na^+ or H^+) attached to the framework which tends to keep the zeolite charge neutral. Due to its high acidity, ZSM-5 is an active heterogeneous catalyst for acid-catalyzed reactions. ZSM-5 membranes have been largely investigated in the literature, for gas separation (e.g., CO_2 (Bernal et al. 2004)), pervaporation (organic dehydration or removal of organics from water), and applications in catalytic reactors (Julbe 2007). Xylene isomerization favoring paraxylene production is a typical example where molecular sieving through ZSM-5 leads to a faster diffusion of the latter. A series of additives has been introduced within the ZSM-5 membranes, either by postsynthetic modification or directly during the synthesis, to modify either the surface properties or the channel size of the zeolite membrane. Catalytic cracking of methyldiethoxysilane is an example of postmodification, yielding attractive H_2 separation properties for the modified ZSM-5 membranes, up to 500 °C (Wang and Lin 2012; Hong et al. 2005).

 Polyelectrolyte Membrane for OSN
 Polyether Block Amide (PEBAX)
 Polyetherimide Membrane
 Polyethersulfone (PES)
 Polyethersulfone Membrane

Polyethylene Membrane
Polyethylene Oxide
Polymer Electrolyte Membrane Fuel Cell (PEMFC)
Polymer Inclusion Membranes
Polymer with Intrinsic Microporosity (PIM)
Polymeric Catalytic Membranes
Polymeric Magnetic Membranes
Polymeric Membrane Characterization by PALS
Polymeric-Ceramic Catalytic Membrane
Polymers for Drug Delivery
Polymers for Tissue Engineering
Polyphenol Recovery from Olive Mill Wastewater by Membrane Separation
Polyphenol Recovery from Wine Wastes by Membrane Operation
Polypropylene (PP)
Polypropylene Membrane
Polyvinylidene Fluoride (PVDF)
Polyvinylidene Fluoride Membranes
Pore Forming Agent
Pore Model
Pore-Through-Flow Catalytic Membrane
Porous Functional Membranes
Porous Membranes
Porous Silicon
Porous Stainless Steel Hollow Fibers
Positron Annihilation Lifetime Spectroscopy (PALS)
Positron Annihilation Spectroscopy
Positron Annihilation Technique
Premix Membrane Emulsification
Pressure Decay Method
Pressure Retarded Osmosis (PRO) for Energy Generation
Pressure-Retarded Osmosis
Principal Component Analysis (PCA)
Principle of Biocatalytic Membrane Reactors (BMR)
Principle of Dialysis
Principle of Electrodialysis
Principle of Gas Separation
Principle of Membrane Contactors
Principle of Membrane Emulsifier
Principle of Membrane Reactors
Principle of Microfiltration
Principle of Nanofiltration (NF)
Principle of Pervaporation

Principle of Reverse Osmosis (RO)
Principle of Ultrafiltration (UF)
Process Control in Membrane Operations
Productivity and Footprint in Gas Separation
Propane Oxidative Dehydrogenation by Membrane Reactor
Propolis Extract Nanofiltration
Proteases in Membrane Bioreactor
Protein Crystallization by Membrane Crystallization
Protein Fouling
Protein Fouling Mechanisms
Protein Purification by Membrane Operations
Protein Recovery by Membrane Operations
Protein Separation by Charged UF Membranes
Protein Separation by UF
Proteins Separation by Membrane Operations
Proton-Exchange Membranes for Fuel Cells
Pulp and Paper Industry and Membrane Operations
Pulp Industry and Membrane Operations
Purification of Plasma from Cholesterol by Immunoaffinity Membranes
PVA-Based Anion-Exchange Membranes

Q

Quantitative Structure-Property Relationships (QSPR)

R

Radiation-Induced Grafting
RAFT Chemistry
Reactive Air Brazing (RAB) for Gas Separation Membranes
Reclaimed Water, Membranes for
Recovery of Antibiotics from Fermentation Broth Membrane Operations
Recovery of Polyphenols from Olive Mill Wastewaters by Membrane Operations
Recovery of Polyphenols from Wine Wastewaters by Membrane Operations
Regeneration of the Ion-Exchange Resin
Regenerative Medicine
Regenerative Medicine by Membrane Operations
Rejection
Release of Antimicrobial Agent
Reliability in Gas Separation

Removal of Antibiotics from Wastewaters by Membrane Operations

Removal of Dissolved VOCs from Aqueous Solutions (Pervaporation Application)

Response Surface Methodology (RSM)

Responsive Membranes

Retentate

Reuse of Paper Mill Effluents, Membranes for

Reverse Electrodialysis (RED)

Reverse Electrodialysis in High Supersaturation Mode

Reversible Flux Decline

Reversible Fouling

Reversible Fouling for Constant Pressure Operation

Reversible Fouling Resistance

Rheology of Emulsions

Richardson Law

S

Sanchez and Lacombe Theory

Sand Filter

Saturated and Supersaturated Solutions

Scale Inhibitor

Screen Printing of Membranes

Secondary Growth Method

Secondary Growth Method for Zeolite Membrane Preparation

SEDE (Steric, Electric, and Dielectric Exclusion) Model: Approximated Versions

Seeded Hydrothermal Synthesis for Zeolite Preparation

Seeding

Seeding for Zeolite Membranes

Segmented Block Copolymer

Self-Bundling Electrospinning Method

Separation and Recovery of Gases, Multistage Process for

Separation of Organic from Organic Components (Pervaporation Application)

Sequential Dilution Diafiltration

Serum Proteins

Shear Stress, Control Fouling with

Sieverts' Law

Silica DDR Membrane

Silica Gel for Membrane Preparation

Silica Membrane

Silicalite Membrane

Silt Fouling Index (SFI)

Silver Recovery by Bulk Liquid Membrane (BLM)

Silylation

Simple Emulsion

Sintering Method for Ceramic Membrane Preparation

Smart Membranes

Soaps

Sol-Gel Method for Ceramic Membrane Preparation

Solid Electrolyte

Solid Electrolyte Membrane Reactor

Solid Lipid Particles

Solubility

Solubility and Partitioning

Solubility Coefficient (S)

Solubility of Gases in Membranes

Solubility Parameter

Solubility-Selective Membrane

Solute Reverse Transport

Solution-Diffusion Mechanism

Solvent Evaporation Membrane Crystallization

Solvent Swollen Polymer

Solvent-Resistant Nanofiltration

SO_x, Effect on Membrane Properties

Spacer Arm Length

Spacer-Filled Channels

Spin Coating

Spin Coating Interfacial Polymerization (IP) Techniques

Spiral Wound Membrane

Spiral Wound Membrane Module

Spiral Wound Module

Sponglike Structure

Spray Coating

Spray-Pyrolysis

SPS/PES Asymmetric Blend Nanofiltration Membrane

Stack of Single Cells in Electrodialysis

Static Membrane Emulsification

Stem Cell

Stimuli Responsive

Stimuli-Responsive Membranes

Strip Dispersion Supported Liquid Membrane

Stripping Agents: Use in Liquid Membrane System

- Strontium: Removal and Recovery by Supported Liquid Membranes
- Structured Membrane
- Structured Reactor
- Styrene-Grafted Film
- Submerged Biocatalytic Membrane
- Submerged Flat-Sheet Module
- Submerged Membrane
- Submerged Membrane Bioreactor
- Sugarcane Juice, UF Application of
- Sulfonated Aromatic Polymer
- Sulfonated Block Copolymer Membrane
- Sulfonated PEEK (SPEEK)
- Sulfonated PEEK-WC (SPEEK-WC)
- Sulfonated PES (SPES)
- Sulfonation Reaction
- Sulfur Odorous Compounds Removal by Pervaporation
- Supercritical CO₂ Hybrid Membrane Systems
- Superhydrophobicity
- Superparamagnetic Properties of Membranes
- Supported Liquid Membrane
- Supported Liquid Membrane for Enantioselective Separation
- Supported Magnetic Ionic Liquid Membranes
- Surface Analysis
- Surface Charge
- Surface Charge Density
- Surface Modification: Chemical Treatment
- Surface Modification: Introduction of Carboxyl Group
- Surface Modification: Wet Chemical Oxidation
- Surface Morphology
- Surface Tension
- Surfactants
- Sweep Gas in a Membrane Reactor
- Sweep Gas Membrane Distillation (SGMD)
- Sweep Gas Membrane Distillation (SGMD) Applications
- Synthetic Biomembrane
- T**
- Tapping Mode
- Temperature Polarization
- Temperature Polarization Coefficient (TPC)
- Temperature-Difference-Controlled Evapomeation (TDEV)
- Temporary Liver Support Systems
- Tensile Strength
- Ternary Pd-Alloy Membranes
- Tetrazole Group
- Texture Recognition
- Thermally Induced Phase Separation (TIPS) for Membrane Preparation
- Thermopervaporation (Thermo-PV)
- Thermoresponsive Membrane Surfaces
- Thin-Sheet Zeolite Membranes
- 3D-Imaging Methods for Membranes
- Three-Dimensional (3D) Microscopy Methods
- Time Lag Method for Mass Transport Properties Evaluation in GS
- Tissue Engineering and Regenerative Medicine
- Tissue Engineering, Membrane Operations of Titania Membranes
- Toluene Removal by PV on Polymeric Membranes
- Toluene Removal by PV Supported Liquid Membranes
- Tomographic Microscopy Methods
- Track-Etch Membranes as Tools for Template Synthesis of Nano-/Microstructures and Devices
- Traditional Diafiltration
- Transient Membrane Transport, Analysis of
- Transparent Exopolymer Particle
- Transport Mechanisms with Liquid Membranes
- Treating Pomegranate Juice, Application of Membrane Processing
- Tricaprylamine
- Tridioctylamine
- Tri-*n*-caprylamine
- Tri-*n*-octylamine
- Trioctylamine
- Triptycene Polymer with Intrinsic Microporosity
- Tubular Membrane
- Tubular Membrane Module
- Tubular Module
- Turndown in Gas Separation
- Two-Dimensional Amphiphilic Aggregates
- Two-Separate Phase Biocatalytic Membrane Reactors
- U**
- UF Membranes (Ultrafiltration Membranes)
- UF Modeling (Ultrafiltration Modeling)

UF Transport (Ultrafiltration Transport)
 Ultrafiltration (UF)
 Ultrafiltration Applications
 Ultrafiltration Membrane Bioreactor
 Ultrafine Nanofibers
 Ultrahigh Molecular Weight Polyethylene
 Urease Immobilization on Membranes
 Use of Microalgae in MBR
 Use of Streaming Potential Measurements for
 Characterization of Both Membrane/
 Electrolyte Interface and Protein Fouling
 Effect
 UV Irradiation

V

Vacuum Membrane Distillation (VMD)
 Vacuum Membrane Distillation (VMD),
 Applications of
 Vacuum-Driven Pervaporation
 Vapor Permeation
 Vapor Plasma Membrane Treatment
 Vapor Pressure–Temperature Relationship
 Variable Volume Diafiltration
 Vertically Aligned Carbon Nanotube
 Vibrating Membranes
 VOC Recovery
 Volatile Organic Compounds (VOCs)
 Volume Concentration Factor
 Volume Index

W

Wash Water in Diafiltration
 Water Competitive Diffusion
 Water Demineralization
 Water Deoxygenation by Catalytic
 Membranes
 Water Desalination in Electrodialysis
 Applications
 Water Disinfection by Membrane
 Operations
 Water Electrooxidation
 Water Gas Shift (WGS)
 Water Purification
 Water Recovery in Paper Industry by Membrane
 Operations
 Water Recovery in the Paper Industry,
 Membranes for

Water Recycling in Electroless Plating by
 Membrane Operations
 Water Reuse
 Water Reuse and Recycling in Pulping Plants by
 Membrane Operations
 Water Sorption and Diffusion
 Water Splitting
 Water Transport in Ion-Exchange Membranes
 Water Treatment by Electrodialysis
 Water Treatment by Membrane Operations
 Wenzel Model
 Wet Chemistry Method for Ceramic Membrane
 Preparation
 Whey Demineralization with Membrane
 Operations
 Whey Processing: Overview and Role of
 Membranes
 Whey Protein Concentrate: Overview and
 Membrane Operations
 Whey Protein Fractionation: Overview and
 Membrane Operations
 Whey Protein Isolation: Overview and Membrane
 Operations
 Whey Ultrafiltration
 White Water Recovery by Membrane
 Operations
 Wide-Angle X-Ray Diffraction (WAXD)
 Wide-Angle X-Ray Diffraction Pattern
 Wide-Angle X-Ray Scattering (WAXS)
 Wine Aroma Enhancement
 Wine Aroma Enhancement, Membrane
 Operations of
 Wine Clarification by Membrane Operations
 Wine Clarification by Microfiltration

X

X-Ray Diffraction (XRD)
 X-Ray Synchrotron
 X-Ray Synchrotron Microtomography

Y

Young's Model

Z

Zeolite A Type
 Zeolite Membrane
 Zeolite Membrane: Synthesis

Zeolite T Type	ZIF
Zeolite X Type	ZIF-8 Membrane
Zeolite Y Type	Zinc Recovery by Supported Liquid Membrane
Zeolite-Embedded Membrane	Zirconium-Phosphate (ZrP)-Filled Nafion
Zeolitic Imidazolate Framework-8	Membrane
Zeta Potential	ZSM-5 Zeolite Membrane
Zeta Potential Measurement
